PUSA

The Analyst

21. NOV
A. R. I.

THE ORGAN OF THE

Society of Public Analysts

A MONTHLY JOURNAL DEVOTED TO THE ADVANCEMENT OF ANALYTICAL CHEMISTRY.

EDITORIAL COMMITTEE:

THE PRESIDENT (BERNARD DYER, D.Sc., F.I.C.).

ALFRED H. ALLEN. OTTO HEHNER.

EDWARD J. BEVAN. THOMAS STEVENSON.

CHARLES E. CASSAL. E. W. VOELCKER.

EDITOR: WALTER J. SYKES, M.D.

VOLUME XXII.

1897.

LONDON:

BAILLIÈRE, TINDALL AND COX,

KING WILLIAM STREET, STRAND, W.C.

ERRATA.

The second paragraph which appears on page 124 is misplaced ; it should be read in connection with the table on page 120, to which it refers.

Page 282, lines 17, 19, and 20. *for* "per cents." *read* "parts per thousand."

Page 326, lines 6 and 9 from bottom, *for* "sulphur chloride" *read* "carbon disulphide."

INDEX TO VOLUME XXII.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS, 10, 38, 71, 104, 129, 157, 189, 211, 235, 263, 282, 322
Acacia, Commercial, 240
Acetic Acid, Determination of, in the presence of inorganic Salts, 309
Acetone, Messenger method of estimating, 74
——— in Urine, Estimation of, 44
Acetylene, Use of, in quantitative analysis, 223
Acid, Acetic, Determination of, in the presence of inorganic Salts, 309
——, Betanaphthalenesulphonic, as a reagent for Albumin, Albumoses, and Peptones, 274
——, Boric, Estimation of, 48
——, ——, Notes on the influence of, upon the action of the Digestive Ferments, 182
in Meat products, Determination of, 282
Carbonic, in natural Waters, Estimation of, 312
Di-Sulphuric, Colour reaction for, 304
Hydrochloric, Purification of, 304
Nitrous, and Nitrites, Estimation of, 304
Oxalic, Preparation of pure, 136
, Preservation of solutions of, 306
—, Phosphoric, "Available," Arsenical Sulphuric Acid a source of error in the Naumann-Wagner process for the estimation of, 48
—, ———, Determination of, as Phospho-Molybdic anhydride, 250
—, ———, New method for the determination of, 333
—, ———, in Thomas Phosphate powder, Determination of the citrate-soluble, 137
—, Salicylic, Estimation of, and its detection in Wine, Beer, etc., 39
—, Sulphuric, Arsenical, a source of error in the Naumann-Wagner process for the estimation of "available" Phosphoric Acid, 48
—, Tartaric, and Potassium bitartrate in Wines, Estimation of free, 284
—, in Wine, New method of estimating, 283
——, Uric, in Urine, Rapid estimation of, 276
——— and Saponification numbers, Proposals with the object of establishing uniformity of procedure in determining the, 243
Acids, Citric and Malic, Detection and extraction of, by means of Quinine and Cinchonine, 107
——, Fatty, and the Hehner number, Apparatus for rapidly estimating, 307
——, Meta- and Pyro-Phosphoric, in dried Superphosphates, Determination of, 111
——, Nitric and Chloric, Colour reactions of, with certain Aromatic bodies, 273
——, Selenious and Selenic, Iodometric determination of, 82
——, Shellac Resin, Behaviour of, in Gladding's and Twitchell's methods, 244

Acids, Sulphoxyarsenic, Reactions of, 304
———, Tartaric, Citric, and Malic, Some colour reactions of, 192
Acridine Red, Effect of, on Digestion, 40
Adrian, L., Rapid method of analysing Guaiacol and Creosotes, 162
———, M., Estimation of Guaiacol by demethylation, 245
Air, etc., Estimation of Oxygen in, 165
Albahary, J., Simple and rapid analysis of Nickel castings; Separation of Nickel and Cobalt by the Von Knorre method, 249
Albane, 329
Albumin, Analysis of commercial, 275
————, Testing commercial, 294
————, Albumoses, and Peptones, Betanaphthalenesulphonic Acid, 274
Albuminoids in Milk, Determination of, 157
———— of Cow's Milk, 211
Albumose, Deutero-, New method for isolating, 289
Albumoses, Albumin, and Peptones, Betanaphthalenesulphonic Acid as a reagent for, 274
Alcohol, Calculation of the results of distillation of, 155
————, Correction of specific gravity of, for expansion, 153
————, Different methods of stating strengths of, 154
————, Ethyl, Distillation of highly-diluted, 263
————, Indirect estimation of, 156
————, Note on the indirect (Tabarie's) method for the estimation of, 225
————, Notes on, 153
———— as a source of error in volumetric analysis, 83
————, Carbon tetrachloride, etc., Estimation of Carbon disulphide in, and a method for the purification of the latter, 246
———— in Milk, Occurrence of, 264
Alcoholic Fermentation, 56
Alcohols, Amyl and Isobutyl, Colorimetric determination of, 285
———— in Spirits, Estimation of the higher, 263
Aldehyde, Formic, Distillation of, from aqueous solutions, 92
Estimation of, 221
Note on the estimation of, 4
Separation and estimation of, 5
Test for, 106
as a reducing agent in analysis, 135
Furfuric, Estimation of, by means of Phloroglucinol, 106
in Ether, Determination of, 221
Aldehydes and Ketones, Colour reactions of, 267
Aldoses, Estimation of, 268
Alkaloidal Extracts, Separation of, 76
Alkaloids, Delicacy of Marmé's test for, 241
————, Estimation of, by titration with Iodine solution, 43
————, New method for the quantitative estimation of, 42
———— in White Hellebore, Estimation of, 239
Allen, A. H., Copper in Foods, 146
————, Determination of Acetic Acid in the presence of inorganic salts, 310
————, Estimation of Carbonic Acid in natural Waters, 317
————, Lead in Cheese, 3
————, Statement of analytical results, 89
————, *and* Cox, F. H., Note on the presence of heavy metals in Cheese, 187
————, —— Searle, A. B., Improved method of determining Proteid and Gelatinoid substances, 258

Allen, Dr. F. J., Antiseptics in Food, 38
Alloxuric Substances (Xanthine bases) in Urine, Krüger and Wulff's process for estimating, 222
Aloes, Determination of Aloin in, 129
Alum in Bread, Detection of, 10
Alumina and Iron, Separation of, by the aid of Sodium peroxide, 278
———— oxide of Iron in Phosphates, Determination of, 166
Aluminium, Separation of Cobalt from, 278
Iron from, 194
and its alloys, Analysis of, 193
Ambühl, G., Gravimetric estimation of Sugar, 106

THE ANALYST.

JANUARY, 1897.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, December 2, 1896, at the Chemical Society's Rooms, Burlington House, the President occupying the chair.

The minutes of the previous meeting were read and confirmed.

Mr. David James Morgan, B.A., was elected a Member of the Society, and Messrs. Percy T. Adams, Louis Charles Deverell, and Percy S. Marshall were elected Associates.

Mr. Frank R. Stephens, analyst to Messrs. Idris and Co., was proposed for election as a Member.

Mr. BEVAN (Hon. Sec.) read the following list of officers for 1897, as nominated by the existing Council:

President: Bernard Dyer, D.Sc.

Vice-Presidents who have filled the office of President: M. A. Adams, F.R.C.S., A. H. Allen, Sir Chas. A. Cameron, M.D., F.R.C.S., A. Dupré, Ph.D., F.R.S., Otto Hehner, Alfred Hill, M.D., F.R.S.E., J. Muter, M.A., Ph.D., F.R.S.E., Thos. Stevenson, M.D., F.R.C.P.

Vice-Presidents who have not filled the office of President: A. P. Aitken, D.Sc., F.R.S.E., W. W. Fisher, M.A., John Pattinson.

Hon. Treasurer: E. W. Voelcker.

Hon. Secretaries: E. J. Bevan, Charles E. Cassal.

Other Members of Council: R. Bodmer, A. Wynter Blyth, M.R.C.S., A. C. Chapman, S. Rideal, D.Sc., J. E. Stead, J. A. Voelcker, M.A., B.Sc., Ph.D.

The names of those members of the Council who do not retire this year are Leonard Archbutt, Bertram Blount, E. Russell Budden, W. J. Dibdin, Sidney Harvey, and Alfred Smetham.

The following papers were read: "Note on Formalin," by Ronald Orchard; "On the Separation and Estimation of Formic Aldehyde," by Norman Leonard, B.Sc., and Harry M. Smith; "Notes on Prussian Blue," by Frank H. Leeds; "The Estimation of Borax and Boracic Acid in Milk," by Frank P. Perkins; "Note on Copper in Oysters," by W. F. Lowe; "The Statement of Analytical Results,' by J. F. Liverseege.

A FURTHER NOTE ON LEAD IN CANADIAN CHEESE.

By F. Wallis Stoddart, F.I.C., F.C.S.

(Read at the Meeting, November 4, 1896.)

On page 208 of the current volume of the Analyst is a report of a short communication I made to the Society on cheese containing lead in what I believed to be largely the metallic condition. The evidence on this point, however, was not of the most conclusive character, as was pointed out by several contributors to the discussion that followed.

The physical characters of the material seemed to limit the possibilities to the metal more or less superficially corroded, the sulphide, and to certain salts such as the carbonate blackened by sulphide resulting from decomposition of the cheese. The difficulty in deciding arose, of course, not so much from the want of analytical methods, as from the impossibility of freeing the matter from adherent particles of cheese. It should be remembered that the total lead amounted only to 1¼ grains per pound of cheese, that most of this was so distributed over the surface of the curds as to be inseparable by scraping, and that any attempt at destruction of the adherent matter defeated the object of the experiment by attacking the pigment.

My reasons for arriving at the conclusion stated were the solubility relations to acids, particularly to dilute nitric acid in the cold, the purity of the oxide obtained on ignition, and the entire failure to detect sulphur in any shape; to these may be added the readiness with which the substance was attacked by caustic alkali in attempts to purify it.

As regards the detection of sulphide, it was suggested by Mr. Allen that a good method consisted in treating with hydrochloric acid in presence of zinc, when sulphuretted hydrogen is readily liberated. This reaction has been applied without demonstrating the presence of sulphide. It seemed, therefore, very desirable to obtain positive evidence as to the condition of the lead, and further consideration has suggested a method which apparently yields decisive results.

It is well known that lead ranks amongst the more electro-positive metals, and that many others, especially silver and copper, are readily deposited upon it from slightly acid solutions. A stick of lead immersed in a slightly acid solution of copper is speedily covered with a closely adherent film of characteristic colour. If this film is scraped off with as little lead as possible, and the metals precipitated from solution in acetic acid with a ferrocyanide, the lead ferrocyanide formed is tinged more or less deeply with the red copper ferrocyanide. This forms an exceedingly delicate test for copper, the least shade of red being very perceptible. Under parallel circumstances, silver is deposited as a brownish black pulverulent coating rather easily detached by rubbing.

It appeared to me that these reactions would be applicable to the problem in hand. By working over ten or twelve pounds of cheese, and selecting the best bits, about half a gramme of material rich in the black pigment was obtained. This was rubbed down in alcohol, and, after decantation of the latter, thoroughly exhausted with ether; it was then washed successively with alcohol and water. After decanting

as closely as possible, the moist residue, consisting now of the pigment with perhaps five times its bulk of casein, was divided into two parts, and treated with silver nitrate and copper sulphate respectively. In a few minutes a distinct change of colour was observable in the silver experiment, the mass taking a brownish shade. Both tubes were left for thirty minutes, then washed with hot water until the washings gave no reactions for metals; the residues were then treated with warm dilute nitric acid, when the filtrates gave abundant reactions for silver and copper respectively. The precipitate of silver chloride so obtained weighed 9 milligrammes, representing about 6 milligrammes of metallic lead. The reaction appeared less complete in the case of the copper.

Now, a possible objection—the only one, as far as I can see—to this experiment is based upon the known affinity of proteids for the heavy metals, notably for copper; and it may be suggested that the casein remaining adherent to the pigment may so far fix either copper or silver as not to yield it to water, though it may subsequently do so to nitric acid. Blank experiments, therefore, were carried out side by side with that described above, using a considerably greater quantity of (*a*) sound portions of the cheese under examination, and (*b*) cheese from an entirely different source. Of these blank experiments, those with silver yielded in the final stage a distinct opalescence of chloride, showing that a trace of silver was rendered insoluble in water. No reaction was obtained with the copper under the same conditions, but a more rigid examination showed that a minute quantity of copper was fixed. The amount, however, in both cases was so minute in comparison with that obtained in presence of the black pigment, as to be negligible for the special purpose in view.

I think, therefore, I am justified in concluding that the black pigment consists essentially of metallic lead, with possibly some superficial sulphide.

As to the origin of this impurity, no light has up to the present been obtained. The most reasonable suggestion seems to be that it is introduced accidentally by friction upon some leaden surface. This explanation would be consistent with the fact that out of a consignment of two hundred cheeses about one hundred and fifty were affected in varying degrees.

An interesting point is that for many months mice refused to eat this cheese, though they repeatedly disposed of the greasy paper in which it was wrapped; and only very occasionally, and to a very limited extent, was the cheese itself attacked. On the other hand, during the last few weeks it has become such a happy hunting-ground for "jumpers," the larvæ of a small black fly, as to necessitate its destruction.

Discussion.

Mr. Allen said it was no doubt a very curious thing that the lead should be present, and one began to speculate as to its origin. He had heard of cheese being wrapped in cloths impregnated with chromate of lead, and it occurred to him to ask if Mr. Stoddart had looked for chromium in any form. It was possible, in the case of the heavy metals, that they might be reduced from such a compound as a chromate to a metallic state by reaction with the organic constituents of the cheese. Personally he was not satisfied as to the condition in which the lead existed, but Mr. Stoddart had taken a great deal of trouble in the matter, and it was not easy to decide as to

the condition of a substance existing in such a finely-divided state and such small quantity in an article like cheese. Whatever its origin might be, however, there could be no doubt as to its existence, and it behoved public analysts to do all they could, in cases like this, to ascertain, if possible, how the impurity came to be present.

NOTE ON THE ESTIMATION OF FORMALDEHYDE.

By Ronald Orchard.

(Read at the Meeting, December 2, 1896.)

Owing to the rapidly increasing importance of formaldehyde, both commercially and as a laboratory reagent, a simple and exact method for determining the strength of its dilute solutions is much needed.

Mr. Harry Smith, in the Analyst for June, 1896, describes a method based on the oxidation of formaldehyde by an alkaline solution of potassium permanganate. But as he admits that it is not reliable for smaller quantities than 0·01 gramme formaldehyde, and that there are considerable difficulties in its manipulation, I have, at Dr. Rideal's suggestion, endeavoured to apply the well-known reaction of formaldehyde with an ammoniacal solution of silver nitrate quantitatively, the precipitated silver being either weighed, or the residual silver determined volumetrically. In the actual experiments 10 c.c. of an approximately 0·1 per cent. solution of formaldehyde were added to 25 c.c. $\frac{N}{10}$ silver nitrate, 10 c.c. of dilute ammonia (1 of the 0·88 solution to 50 of water) added, and the whole boiled in a conical flask attached to a reflux condenser. The precipitate, after filtration and washing, was ignited and weighed as metallic silver, and as a check the excess of silver was estimated in the filtrate as silver chloride. As the first experiments showed that the reduction was incomplete after boiling for half an hour, the boiling was continued for four hours. In order to ascertain if any loss took place during boiling, a duplicate determination was made, in which a bottle with tied-down stopper, heated in a water-bath, was employed. The actual results obtained were in the first case 0·01038 gramme formaldehyde, and in the second 0·0104 gramme formaldehyde, consequently there was practically no loss.

In the calculation, as one molecule of CH_2O reduces two molecules of Ag_2O, the weight of the precipitated silver multiplied by the factor 0·0694, gives the weight of the formaldehyde, and 1 c.c. of $\frac{N}{10}$ silver nitrate corresponds to 0·0007495 gramme formaldehyde; it is therefore possible to estimate extremely small quantities by this process.

The following are some duplicate results obtained:

	Percentage CH_2O.	
Approximately 0·1 per cent. solution	(i) 0·1038	(ii) 0·104
Samples of milk-formalin, No. 1	(i) 1·09	(ii) 1·07
,, ,, ,, ,, 2	(i) 0·98	(ii) 0·96
,, ,, ,, ,, 3	(i) 1·02	(ii) 1·02

Incidentally the above results show that the dilute "formalin" supplied for preserving milk which was employed in the experiment is fairly constant in strength.

ON THE SEPARATION AND ESTIMATION OF FORMIC ALDEHYDE.

By Norman Leonard, B.Sc., and Harry M. Smith.

(*Read at the Meeting, December* 2, 1896.)

Some months ago one of us (Analyst, xxi., 148) described a process for the estimation of formic aldehyde, depending upon the oxidation of that substance into formic and carbonic acids by potassium permanganate in alkaline solution. This process we have endeavoured, according to an intention stated in the paper referred to, to apply to the estimation of formic aldehyde in milk, and in doing so we have obtained certain results which seem worthy of notice.

It was of course necessary, in the first place, to ascertain whether pure milk yielded, when distilled, any substance capable of reducing alkaline permanganate Examination of four different samples showed that the distillate from fresh milk exerts practically no such reducing action. The distillate from 100 c.c. of milk required, in fact, scarcely more permanganate than is necessary to give the colour indicating the end-point of the titration. Milks which had been kept several days, still more sour and decomposed milks, yielded appreciable amounts of organic matter on distillation. The process is therefore only applicable to fresh milk.

Several experiments were made on the distillation in a current of steam of milk and aqueous solutions, to which a known amount of formic aldehyde had been added. The recovery of the aldehyde was, however, slow and unsatisfactory. We found, for example, on thus distilling 100 c.c. of liquid containing 0·01 per cent. of formic aldehyde, that the first 50 c.c. of the distillate contained only one-fourth of the total amount of aldehyde added, while less than three-fourths had passed over even when 300 c.c. of distillate had been collected. Simple distillation, though rather more troublesome, was therefore resorted to. The results of three experiments with milk are here tabulated. In each case 100 c.c. of milk was distilled, the distillate being collected in fractions of 20 c.c., each of which was titrated with permanganate solution. The residue remaining in the retort was examined for formic aldehyde by Hehner's test. In the second and third experiments, the liquid was rendered acid and alkaline by the addition of a few drops of dilute sulphuric acid and of caustic soda solution respectively:

	Neutral. Grammes CH_2O.	Acid. Grammes CH_2O.	Alkaline. Grammes CH_2O.
First 20 c.c.	·0015	·0026	·0011
Second 20 c.c. ...	·0006	·0019	·0004
Third 20 c.c.	·0002	·0011	·0003
Residue...	none	present	none
Aldehyde added	·0090	·0090	·0094

It will be noticed that the presence of acid greatly facilitates the expulsion of the aldehyde, while that of alkali tends to retard it. Moreover, the aldehyde was only detected in the residue of the second experiment, in which acid was added. These facts indicate, perhaps, the formation of compounds of the aldehyde with some constituent of the milk, such compounds being broken up, or their formation prevented, by addition of acid.

In these experiments we were somewhat struck by the slowness with which the formic aldehyde, commonly regarded as a very volatile body, distilled over, and we therefore carried out three similar distillations of *aqueous* solutions of the aldehyde. The results are given below. The aldehyde contained in the residue remaining in the retort was in each case determined :

	Neutral. Grammes CH_2O.	Acid. Grammes CH_2O.	Alkaline. Grammes CH_2O.
First 20 c.c.	·0024	·0023	·0026
Second 20 c.c.	·0021	·0018	·0020
Third 20 c.c.	·0017	·0017	—
Fourth 20 c.c.	·0011	·0012	—
Residue...	·0005	·0006	·0031
Total	·0078	·0076	·0077
Aldehyde added	·0078	·0078	·0078

The presence of acid or alkali is here seen to exert little or no influence upon the rate of distillation ; and it appears that the aldehyde is not completely expelled from its solutions by anything short of distillation to dryness. This result might perhaps have been anticipated if we may reason by analogy from the results obtained by Duclaux, and also by Richmond, in the distillation of the fatty acids of the acetic series.

Our experiments lead us to conclude that :

(1) The distillate from fresh milk exerts no appreciable action on alkaline permanganate, and can therefore be used for the estimation of formic aldehyde, the absence of other volatile organic bodies being assumed.

(2) The separation of formic aldehyde from milk by distillation is facilitated by acidulation with sulphuric acid. Under these conditions, the first 20 c.c. of distillate from 100 c.c. of milk will contain about one-third, and the first 40 c.c. about one-half, of the total amount of aldehyde present.

(3) The fact, which has often been adverted to, that the formalin contained in the distillate from milk does not represent the whole of that originally added, is to a great extent explained by the behaviour of solutions of formic aldehyde on distillation, and is only partially due to any specific action of the aldehyde on the constituents of milk.

Discussion.

The President thought it would be interesting if the authors of the first paper could furnish any observations upon the application of their process to milk and other products. So far the paper only dealt with the estimation of formaldehyde in aqueous solution.

In the second paper it seemed to be implied that there was a combination between the formaldehyde and the milk. It was a known fact that formaldehyde polymerized on heating, and it might be that, during the operation of distilling, the formaldehyde polymerized into a molecule more condensed, and more difficult to decompose, than the original molecule.

Mr. Hehner, alluding to a paper which he had some time previously read before

the Society, describing the method which had been referred to as his, said that many people had found difficulty, at first, in obtaining the special reaction with sulphuric acid in the case of milk containing formaldehyde. A suggestion made by one of the authors of the second paper had led to this difficulty being overcome. The suggestion related to the addition of a trace of ferric chloride, which greatly facilitated the reaction.

Apart from the difficulty of distilling formaldehyde from aqueous solution, there was no doubt that formaldehyde combined with certain albuminous substances. He had no experience of its action upon casein, but it certainly combined with albumin to yield a substance which did not coagulate by heat. A solution of albumin containing formaldehyde could be evaporated to dryness, the residue left being completely soluble in water. A process involving this principle had lately been patented. The inventor's conclusion was that two molecules of the albumin were condensed by formaldehyde, the resulting compound being a methylene derivative albumin.

If this conclusion were correct, it would explain why it was not possible to recover the whole of the formaldehyde added to an albuminous substance like milk, since a portion of it would have undergone change in forming the methylene derivative.

Mr. RICHMOND said that almost all organic compounds containing the $-NH_2$ (or $=NH$) group condensed with formaldehyde in the same manner as albumin. Aniline, for instance, gave a compound which was known by the name of anhydro-formaldehyde-aniline, $C_6H_5NH_2 + CH_2O = CH_2NC_6H_5 + OH_2$.

The figures given by Messrs. Leonard and Smith, in relation to fractional distillation, showed that formaldehyde conformed to the law which he had worked out for the volatile acids of the acetic series.

It was curious that higher results should be obtained from acid solutions. The substance liberated by the acid was probably not formaldehyde, but some substance which distilled at about the same rate as water. It would be interesting if some knowledge could be obtained as to the exact nature of this substance, as it would probably throw some light on the changes taking place when formaldehyde and milk were mixed and kept for some time.

Mr. CASSAL said there was no doubt that the addition of formaldehyde to milk profoundly affected the casein. He had made experiments with a view to finding whether the casein was subsequently soluble, and would submit to peptic digestion, and had found that the treatment of milk with the formaldehyde solution in the quantity prescribed by the vendors made the milk indigestible. It curdled into a condition of practical insolubility to peptic digestion. A similar effect was produced on gelatin, which was converted, by weak solutions of formaldehyde, into a hard material resembling brittle horn.

With regard to the separation of formaldehyde from milk, there could be no doubt that, as Mr. Hehner had said, it would be impossible to recover the whole amount added to a sample of milk. It was perfectly obvious that if the formaldehyde entered into combination, something must be done to liberate it.

He would like to ask if Messrs. Leonard and Smith had tried repeated distillations by steam. He understood there was only one continuous distillation in their process.

Some time previously Mr. Bevan had called attention to the fact that an increase in the weight of the residue obtained in milk analyses was found when formaldehyde had been added. As a matter of fact, if a solution of formaldehyde were allowed to evaporate spontaneously, a solid substance remained. How far that might account for what Mr. Bevan found he did not know. He believed, however, that complete reproduction of the formaldehyde could be arrived at by means of repeated distillation with water.

Mr. RICHMOND asked to be allowed to submit to Mr. Cassal a question regarding the indigestibility of casein, viz., whether Mr. Cassal had attempted to prove that the undigested casein was not the well-known dyspeptone. It was a matter of common knowledge that, on submitting casein to peptic digestion, especially in milk which contained a large quantity of lime, an insoluble substance in combination with lime was formed. Had Mr. Cassal made any comparative experiments before and after the treatment with formaldehyde? He, in conjunction with Mr. Boseley, had raised the same question with regard to the experiments of Weigle and Merkel on the same lines as Mr. Cassal.

Mr. CASSAL said that his experiments were carried out side by side, the one with milk containing formaldehyde, the other without. He had not done more than this.

Mr. HEHNER said it was a curious fact that the compound formed by the action of formaldehyde on albumin was eminently digestible. He had seen the results of experiments, which he had every reason to believe were carefully performed, showing that the compound was more digestible than ordinary albumin.

Mr. CASSAL pointed out that Mr. Hehner had said that only a certain amount of the formaldehyde entered into combination, and this combination he considered was somewhat theoretical; consequently there would still be a definite proportion of formaldehyde remaining. He suggested that it was to this extra amount that the preservative effect was due, and also the injurious effect which he referred to

Mr. BEVAN said that, considering the large quantity of casein present in milk, and the small quantity of formaldehyde usually added, it was surprising that any of the latter was obtained at all.

Mr. LEONARD, referring to the President's remarks, said that he understood the product of polymerization was readily converted back into the aldehyde by warming with hot water.

In reply to Mr. Cassal, in the case of the steam distillation, a current of steam was passed into the milk, the operation being continued for several hours. It was not repeated, but was a single continuous operation.

The PRESIDENT, in returning the Society's thanks to the authors of the two papers, remarked upon the important part which formaldehyde played in organic nature, instancing its effects upon gelatin, which had been applied in the practical processes of photography, and its quite different action, which Mr. Hehner had pointed out, in relation to albumin. There were many points requiring elucidation in connection with the subject, which offered an encouraging field of research for young investigators.

NOTES ON PRUSSIAN BLUE.

By Frank H. Leeds, F.I.C.

(*Read at the Meeting, December* 2, 1896.)

A study of the figures given by Messrs. Parry and Coste (Analyst, xxi., 225) as representing the composition of commercial Prussian blue, and more especially the manner in which the authors use the term "pure" blue in its chemical as opposed to its trade significance, have made it seem worth placing on record the experience gained of this substance in the laboratory of a printing-ink works, where the pigments employed have to undergo a more rigorous examination than is perhaps necessary in the case of oil paints.

In the manufacture of printers' ink the material known to chemists as "Prussian" blue is used for two distinct purposes: (1) in the production of a blue ink to be sold as such, and (2) in the preparation of the better qualities of black ink as a means of correcting the invariable brown shade of lamp-black. In this trade Prussian blue is met with under four different names: bronze, pure, Chinese, and "Prussian" blue; but although all of these are equally pure from the laboratory point of view, each variety possesses, when ground in "varnish," a distinct shade of colour, consequently they rank, from the printers' standpoint, as four individual pigments. Bronze blue is the basis of that dark-blue ink so often seen on small advertisements and the covers of magazines, which is specially valued for the coppery lustre, or bronze, it possesses when viewed at the proper angle, more particularly when the impression has been made by lithography. Pure blue yields almost the same shade of ink, but devoid of bronze, and it is therefore seldom used except in making black inks. Both kinds have much the same appearance when in the lump or powder, and it is exceedingly difficult to judge the amount of bronze any ink will have from a mere inspection of the dry pigment. In fact, the material having the most pronounced coppery lustre is usually known as Chinese blue; but this, when ground in oil, produces a brighter and slightly paler cast of blue, almost devoid of bronze. "Prussian" blue is not so often met with; it yields a much darker, duller shade of ink, more resembling indigo as a water-colour pigment, and some samples contain a considerable excess of basic ("extra-radicle") iron. Both pure and bronze blues may be obtained in several slightly different shades, varying from the green to the violet side of blue itself.

A regular examination, extending over several years, of the bronze and pure blues supplied by the leading manufacturers has shown that this pigment varies in composition even less than the samples quoted by Messrs. Parry and Coste; but at the same time it has amply proved that the substance may be accurately valued—apart from the question of shade proper—according to the proportion of acid ("intra-radicle") iron it contains. With the exception that no nitrogen estimations were made, the samples were analysed in the manner given in the paper referred to, but as alumina was almost invariably found to be present in the basic iron precipitate, and titrations showed that it was practically constant in amount, it was usually returned simply as Fe_2O_3, both acid and basic iron solutions being always oxidized with nitric acid before the final precipitation with ammonia. Occasionally a sample containing

up to 20 per cent. of an inert white base is offered under the name of "pure blue"; but this must be regarded either as a mis-description or an adulteration, for such a material is well known under its correct designation of "Antwerp" blue. The average figures obtained on the analysis of the best qualities of these pigments, after drying at 100° C., are given below, and from these it would appear that the previous authors' generalizations are perfectly correct, but that their requirement of 30 per cent. of total iron should be increased to 34 per cent., or preferably that at least 16 per cent. of acid iron should be insisted on.

Pigment.		Basic iron per cent.	Acid iron per cent.
Genuine blues: (bronze, pure, or Chinese).	maximum	19·14	17·16
	minimum	18·37	15·35
	mean	18·90	16·48
"Prussian" blue	,,	22·83	10·01
Adulterated "pure" or Antwerp blue	,,	13·41	12·84

DISCUSSION.

Mr. J. H. COSTE expressed satisfaction at the extent to which, so far as could be gathered from the portion of the paper read, the results obtained by Mr. Parry and himself had been corroborated by Mr. Leeds, whose experience on the subject was much greater than their own.

In their paper they had made some remarks on the appearance of the samples they had analysed, some of which had, in the lump, a bright, coppery appearance, while others, though having a glossy conchoidal fracture, were rather bituminous in appearance. When ground up, however, the samples possessing the bright lustre were by no means the darkest blues, and he thought that was what Mr. Leeds stated. The bright coppery blues, as No. III. in our tables, possessed when ground a much finer colour than the darker, more bituminous colours, as, indeed, did the granular, non-lustrous blues. It was a noteworthy fact that the darker samples contained *alkaline* ferrocyanide.

They considered that the nitrogen determination was a very simple, and at the same time sufficiently accurate, method of estimating, for ordinary painters' purposes, the value of samples of Prussian blue. It could be made very quickly, possessing in this respect a distinct advantage over the determination of the total iron. In the case of pigments ground in oil the percentage of nitrogen had been found to afford a ready means of arriving at a very good idea of the actual quantity of Prussian blue that might be present.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

The Detection of Alum in Bread. J. Vanderplanken. (*Ann. d. Ph. Louvain*; through *Zeit. Nahr. Unters.*, Vienna, 1896, x., 316.)—In order to avoid the effect of the acidity of old meal or of sour bread on the logwood test, the author recommends the following method: From 10 to 20 grammes of the bread are triturated into a

paste with water, some sodium chloride (free from alkali) added, and then, after the addition of 10 drops of freshly prepared logwood tincture, 5 grammes of pure potassium carbonate gradually mixed in. After being well mixed, the whole is washed with 100 c.c. of water into a beaker, and allowed to settle. After a few minutes the supernatant liquid shows a reddish violet tint when alum is absent, and a grayish blue to a deep blue when it is present. The reaction is capable of detecting 1 gramme of alum in a kilogramme of bread. C. A. M.

The Estimation of Starch in Sausages. J. Mayrhofer. (*Forsch. Ber.*; through *Zeit. Nahr. Unters.*, Vienna, 1896, x., 331, 332.)—The method hitherto employed for the estimation of meal and other starch-containing substances in sausages has been the inversion of the starch present and determination of the sugar produced. Since this, in the author's opinion, is too tedious, and often unsatisfactory, he brings forward in its place the following simple process: The substance under examination is heated on the water-bath with alcoholic potash (about 8 per cent.), which in the case of pure sausages dissolves almost everything except a little cellulose. The solution is diluted with warm alcohol, to prevent gelatinization, and filtered through a paper or asbestos filter. The insoluble residue, containing the starch when present, is washed with alcohol until the washings are no longer alkaline, then treated with *aqueous* potash, and the starch solution made up to a definite volume. On adding alcohol to an aliquot portion, the starch falls as a flocculent precipitate, which rapidly subsides. This is collected on a weighed filter, washed with alcohol and ether, dried and weighed.

In order to avoid a determination of the ash, it is advisable to make the starch precipitation from a weak acetic acid solution instead of from an alkaline solution, since the acetate formed from the potassium carbonate in the starch is readily soluble in alcohol. By this means the starch is obtained quite free from ash.

From 60 to 80 grammes of the sausage should be taken for the determination, since the starch is usually not regularly distributed throughout the mass.

As a test of the accuracy of the method, mixtures were made of about 60 grammes of sausage, with varying amounts of pure potato starch dried at 100° C., and analysed as described above, with the subjoined results:

Starch added. Gramme.	Starch found. Gramme.
0·058	0·056
0·133	0·132
0·097	0·097
0·098	0·098
0·341	0·340
0·260	0·255

C. A. M.

A New Method of estimating Casein in Milk. G. Denigès. (*Bull. Soc. Chim.*, 1896, 1116-1126.)—This is an application of the author's general process for the estimation of mercury (ANALYST, xxi., 303). On adding to a solution of

potassium cyanide (equivalent to $\frac{N}{10}$ silver nitrate) 10 cc. of an $\frac{N}{10}$ solution of mercuric potassium iodide, 10 cc. of ammonia, and 100 cc. of water, and running in $\frac{N}{10}$ silver nitrate solution, the amount of the latter required to produce a permanent turbidity will not be 10 c.c., but only 4·8 c.c. If, then, the casein in a milk be precipitated by the addition of $\frac{N}{10}$ mercuric potassium iodide and acetic acid, and the excess of mercury determined with silver nitrate, the amount of mercury combined with the casein will be equivalent to $(q - 4{\cdot}8)$ c.c. of $\frac{N}{10}$ silver nitrate.

Twenty-five c.c. of the milk are placed in a 200 c.c. flask, 20 c.c. of $\frac{N}{10}$ mercuric potassium iodide and 2 c.c. of glacial acetic acid added, and the liquid made up to the mark, and filtered. To 100 c.c. of the clear filtrate, 10 c.c. of potassium cyanide solution (equivalent to $\frac{N}{10}$ silver nitrate) are added, and the liquid titrated with $\frac{N}{10}$ silver nitrate, the results being expressed in tenths of a c.c. after the deduction of the constant 48 $(q - 48)$.

The $\frac{N}{10}$ mercuric potassium iodide solution is prepared by dissolving 13·55 grammes of mercuric chloride and 36 grammes of potassium iodide in distilled water, and making up to a litre.

In order to obtain the value of $(q - 48)$, a large number of determinations were made with different kinds of milk, a simultaneous estimation of the casein being made in every instance by the Adam-Roux process, and it was found that $(q - 48)$ did not vary in exact proportion with the amount of casein in the milk, but that for milks rich in casein it was less than the number which gave the real amount of casein per litre, and was greater for poor milks. This variation is plotted in a curve, in which the quantities of casein per litre of milk, x, form the ordinates, and the corresponding values of $(q - 48)$ the abscissæ. From the curve the author has established the following table of relation between x and the values of $(q - 48)$:

$\frac{N}{10}AgNO_3$ in $\frac{1}{10}$ c.c.'s.	Casein. Grammes per litre.	$\frac{N}{10}AgNO_3$ in $\frac{1}{10}$ c.c.'s.	Casein. Grammes per litre.	$\frac{N}{10}AgNO_3$ in $\frac{1}{10}$ c.c.'s.	Casein. Grammes per litre.
0	0	16	14	32	32
1	1	17	15	33	33·50
2	1·7	18	16	34	35
3	2·5	19	17	35	37
4	3	20	18	36	39
5	3·75	21	19	37	40·50
6	4·50	22	20	38	42·75
7	5·50	23	21	39	45
8	6·50	24	22·25	40	47
9	7·15	25	23·50	41	49
10	8	26	24·75	42	51·50
11	9	27	26	43	54
12	10	28	27	44	57·20
13	11	29	28	45	60
14	12	30	29·25	46	62·50
15	13	31	30·75		

In the following tabulated determinations, the results, calculated from this

volumetric method, are compared with those obtained by the gravimetric process of Adam-Roux:

Milk.	$\eta - 48$.	Casein. Weighed. Grammes.	Casein. Calculated. Grammes.	Difference. Grammes.

From these and other experiments, the author concludes that the method is applicable to all possible cases with the exception of milks containing formaldehyde, which exercises a disturbing influence.

Without having recourse to the table or the curve, the corrections may be made simply in the following manner: When $(q - 48) = a$, lies between 9 and 24, $x = a - 2$, that is to say, the constant 2 must be subtracted from the number of tenths of a c.c. of $\frac{N}{10}$ silver nitrate used. When a lies between 25 and 32 inclusive,

$$x = a - \frac{32 - a}{4} = \frac{5a - 32}{4}.$$

And where a is above 33, $x = 2a - 33$. In cases where a is above 37, it is advisable to dilute the milk by one-half, since the method is more sensible with dilute than with concentrated solutions of casein.

It is claimed that this method can be carried out in five minutes, whilst the gravimetric method requires three or four hours. The fact that the caseins from the different milks, although dissimilar in appearance, behave in an absolutely identical manner towards mercuric potassium iodide points to a great similarity, if not complete identity, between them all. The author is examining the application of this process to the determination of other albuminoid bodies. C. A. M.

The Chemical Examination of Cheese. A. Stutzer. (*Zeit. anal. Chem.*, 1896, xxxv., 493-502.)

Ash and Mineral Matter.—From 10 to 15 grammes of the cheese are burnt (preferably in a muffle-oven) in a platinum basin. The weighed ash is dissolved in 250 c.c. of water, and aliquot portions used for the determination of chlorine, calcium and phosphoric acid.

Water.—A weighed quantity of the cheese is mixed with washed, ignited, and sifted quartz sand. For most cheeses the proportions of 100 to 400 grammes of sand are satisfactory, but with very rich cheeses 500 grammes of sand are taken. This sand mixture is used in all the estimations. For the determination of the water, an amount of the mixture corresponding to about 3 grammes of cheese is dried to constant weight in the water-oven.

Fat.—The dry residue from the water-determination is extracted for twenty-four hours with water-free ether, which has been treated with sodium. The author considers that there is less chance of error by this method than in that of Fleischmann, which is frequently employed.

Nitrogen.—I. *Total Nitrogen.*—Ten grammes of the sand-mixture are analysed by Kjeldahl's method. The author considers it preferable to remove the fat first, but mentions that Bondzynski (*Landw. Jahrbuch der Schweiz*, 1894, 197) obtained bad results when doing this.

II. *Applicability of Copper Hydrate to the Precipitation of Albuminoids.*—While copper hydrate can often be used to separate albuminoids from amido compounds

and ammonium salts, the author showed in a former communication (*Zeit. anal. Chem.*, xxxi., 505) that it only partially precipitated pancreas peptone (Kühne's peptone). Thinking that cheese peptone might differ in this respect from flesh peptone, he extended his experiments to the former; but having experienced the same difficulty, he concluded that copper hydrate was not a suitable precipitant for cheese albuminoids, since the latter contained pancreas peptone (Kühne's peptone).

III. *Phospho-tungstic Acid as a Precipitant.*—Bondzynski's conclusions (*loc. cit.*) as to the value of phospho-tungstic acid as a separating agent are confirmed. By its means the caseins and albumins and their primary decomposition products (including the albumoses and peptones) are separated from the worthless decomposition products—phenyl-amido-propionic acid, tyrosine, leucine, and other amides—as well as from the ammoniacal compounds.

The substances belonging to the first group may be further divided into (*a*) Indigestible nitrogenous matters, (*b*) Albumoses and peptones soluble in boiling water, and (*c*) Caseins and albuminates insoluble in boiling water.

IV. *Nitrogen in the form of Ammoniacal Salts.*—An amount of the sand-mixture corresponding to 5 grammes of the cheese is mixed with 200 c.c. of water, and the ammonia distilled after the addition of barium carbonate. Magnesia and magnesium carbonate (which usually contains some magnesia) cause a partial decomposition of the amides.

V. *Nitrogen in the form of Amides.*—This is taken to be the nitrogen belonging to those compounds in the cheese which are not precipitated by phospho-tungstic acid, and which are not ammoniacal compounds. An amount of sand-mixture corresponding to 5 grammes of cheese is mixed with 150 c.c. of water, and well shaken for fifteen minutes in a closed vessel. After standing for fifteen hours at the ordinary temperature, 100 c.c. of dilute sulphuric acid (1 vol. : 3 vol. water) are added, and phospho-tungstic acid so long as a precipitate results. The liquid is filtered, the precipitate washed with dilute sulphuric acid until the filtrate amounts to 500 c.c., and the nitrogen is determined in 200 c.c. of this. By deducting from the amount that previously found as ammoniacal nitrogen, the nitrogen present in the form of amides is obtained.

VI. *Indigestible Nitrogenous Substances.*—The fresh mucous membrane of pigs' stomachs (preferably six) is cut into small fragments and mixed with water and hydrochloric acid in a wide-necked flask in the proportion of 5 litres of water and 100 c.c. of 10 per cent. (by weight) hydrochloric acid to each stomach. At the same time, 2½ grammes of thymol dissolved in alcohol are added as a preservative. The mixture is left for twenty-four hours, with occasional shaking, and then filtered through flannel, coarse paper and fine paper successively. If necessary, the amount of hydrochloric acid in the extract is brought to exactly 0·2 per cent. As thus prepared, the gastric juice remains unaltered for months.

Sand-mixture containing 5 grammes of cheese is deprived of its fat by extraction with ether, mixed with 500 c.c. of the gastric juice in a beaker, and the mixture warmed for forty-eight hours in a thermostat at 37°–40° C. At intervals of about two hours, 5 c.c. of 10 per cent. hydrochloric acid are added, until the acidity of the whole reaches 1 per cent. The liquid is then filtered through paper or asbestos, the

residue washed with water, and the nitrogen contained in it determined. According to Kühne (*Landwirths. Versuchsstat.*, xliv., 194), subsequent treatment with alkaline pancreatic extract is unnecessary when the acid pepsin digestion has been continued for forty-eight hours.

VII. *Nitrogen in the form of Albumose and Peptone.*—A weighed quantity of sand-mixture, containing 5 grammes of cheese, is extracted by boiling with successive portions (100 c.c.) of water, the liquid made up to 500 c.c. and filtered, and 200 c.c. of the clear filtrate, mixed with an equal volume of dilute sulphuric acid, and precipitated with phospho-tungstic acid.

Qualitative Test for Pancreas Peptone.—A portion of the hot-water extract is concentrated by evaporation, saturated with zinc sulphate (ANALYST, xxi., 16), and filtered. Concentrated sodium hydrate is added to the filtrate until the zinc hydrate dissolves, when a few drops of a 1 per cent. solution of copper hydrate are added; the biuret reaction points to the presence of pancreas peptone. The quantitative estimation is carried out as described by the author in his former communication (ANALYST, xx., 249), using Bömer's zinc sulphate modification (ANALYST, xxi., 16).

VIII. *Caseins and Albumins.*—The nitrogen present in these substances, which are insoluble in boiling water, is obtained by subtracting from the total nitrogen the amounts found in V., VI., and VII. It is not advisable to use the residue from the extraction in VII. for the purpose, since the large amount of sand causes violent bumping in the Kjeldahl flask.

IX. *Separation of the Caseins and Albumins Digestible with difficulty from those readily Digestible.*—Cheese contains only small quantities of completely indigestible nitrogenous substances, and it is therefore useful to determine the comparative digestibility of the caseins and albumins. For this purpose a process of "interrupted digestion" is employed. In order to obtain comparable results, care is taken to have constant (1) the amount of nitrogen in the form of insoluble, but digestible, casein and albumin; (2) the amount of gastric juice; and (3) the acidity of the liquid, and the temperature and duration of the digestion.

In each experiment, so much of the sand-mixture is taken as contains 0·15 gramme of nitrogen in the form of insoluble, but digestible, casein and albumin, to which is added 150 c.c. of the gastric juice, with 343 c.c. of water and 7 c.c. of 10 per cent. hydrochloric acid. The acidity of the total liquid ($\frac{1}{2}$ litre) is exactly 0·20 per cent., the temperature is maintained at 37° to 40° C., and the duration of the digestion is thirty or sixty minutes. The liquids are warmed to 40° C. before being measured and after mixing. At intervals of five minutes during the digestion the liquid is stirred with a glass rod; and at the conclusion the total liquid is placed in two large folded rapid filters, and a portion of the filtrate passing through in the first five minutes taken for the determination of the nitrogen. From the result, a deduction must be made for the nitrogen contained in the gastric juice, and for the nitrogen in the cheese dissolving without the aid of the gastric juice (amide, ammoniacal, albumose, peptone).

The following results obtained in the examination of three varieties of cheese illustrate this investigation:

	Camembert. Per cent.	Swiss. Per cent.	Gervais. Per cent.
Water	50·90	33·01	44·84
Fat	27·30	30·28	36·73
Fat-free organic matter	18·66	31·41	15·48

C. A. M.

Analysis of a Spurious Roasted Coffee. M. Maljean. (*Jour. Pharm. Chim.*, 1896, 352-355.)—This product, which was sold by a Marseilles firm under the name of "roasted grains," closely resembled the genuine coffee-bean in appearance and form, and, although close inspection could detect the difference, might easily escape notice when mixed with true coffee. The grains were of a maroon colour, very hard, and very much more regular than coffee-beans. On close examination a seam could be observed in all of them exactly in the middle, and, as a rule, not reaching to the edges, which evidently showed that the grains had been formed by pressure in a mould.

A mixture of the false grains with true coffee could be easily detected by placing it in water, when, owing to their greater density, the former sank.

On being boiled with water for thirty minutes the false coffee did not disintegrate, but only softened; but on being left for several hours in contact with a solution of sodium hydrate, it swelled up, and finally formed a paste. This did not occur with true coffee.

The analysis of the grains (not dried) gave the following results:

	Per Cent.
Water	10·00
Fat	1·90
Nitrogenous matter	13·12
Aqueous extract (20·25), containing Sugar	1·87
Aqueous extract (20·25), containing Gum	5·20
Aqueous extract (20·25), containing Tannin	0·18
Aqueous extract (20·25), containing Other soluble matter ...	13·00
Starch...	47·63
Caffeine	0·00
Cellulose	3·70
Ash	3·40

The ash was neutral, and contained:

	Per Cent.
Part soluble in water	10·30
,, insoluble ,, ...	89·70
Phosphoric acid	23·814
Sodium chloride	0·20
Silica	14·70

The fat was yellow and odorless, and had a consistence similar to that of the fat from flour.

The author came to the conclusion that the false grains consisted of an intimate mixture of meal with bran, and an unknown oleaginous seed of little value, and that the mixture was roasted and subsequently agglutinated with gum or dextrin in special moulds. The gluten in the flour employed would also help to give to the grains their great cohesion. C. A. M.

A Contribution to the Study of Maté. P. Macquaire. (*Jour. Pharm. Chim.*, 1896, 346-350.)—It is shown that maté is a plant which only yields its soluble matter with great difficulty to hot water, and that even after many successive decoctions of twenty minutes each with water at 80° C., a large amount of the soluble substances are left in the residue. The first extract, however, contains nearly the whole of the alkaloid present, whilst the tannin is also found almost entirely in the first decoctions. The subsequent extracts consist chiefly of various resinous bodies, only slightly soluble in water, but readily soluble in chloroform and ether. On treatment of maté with boiling chloroform, the author obtained 10·83 per cent. of a resinous body, only slightly soluble in water and acids, but very soluble in alkalies.

After preliminary trials as to the best method of estimating the caffeine, the following was adopted: An excess of ammonia was added to the aqueous extract of the maté, and the mixture shaken with successive portions of chloroform in a separating funnel. The chloroform extracts were evaporated to dryness, the residues taken up with hot dilute sulphuric acid (1 : 10), the solutions filtered, evaporated to dryness, and the residue again taken up with chloroform, which on being evaporated left the caffeine pure. By this process the author obtained 8·75 grammes of caffeine per kilogramme. He concludes that it is essential to use a large excess of water to dissociate the caffeine from its combination, and in this confirms the statements of

Petit on the estimation of caffeine in tea (ANALYST, xxi., 232). The colour reactions and melting-point of the pure alkaloid (234° C.), and the fact that the melting-points of crystals obtained by fractional crystallization from chloroform were identical, prove that the alkaloid in maté really is caffeine.

The sample of maté examined contained 6·113 grammes of mineral matter per kilogramme, of which 2·82 grammes were soluble in water, and 3·293 grammes insoluble. A considerable quantity of iron was present. C. A. M.

ORGANIC ANALYSIS.

A Study of the Methods for the Determination of Starch. H. C. Sherman. (*School of Mines Quarterly*, 1896, xvii., 356-365.)—The wide distribution of pentosans such as xylan and araban, and their susceptibility to hydrolysing agents, accounts for the high results often obtained by most of the methods for the determination of starch in the presence of other insoluble matter (fibre). In the present paper the author has examined the accuracy of the various methods, with special reference to the pentosans.

The starch solutions were tested in each case by the furfurol test, and when a negative result was obtained it was concluded that no error was introduced from this cause. About 25 c.c. of the solution to be tested were placed in a beaker, with the same volume of 25 per cent. hydrochloric acid, the beaker covered with a watch-glass, and its contents heated to boiling. On introducing a slip of filter-paper moistened with aniline acetate (made by mixing equal volumes of aniline and strong acetic acid) into the escaping vapours, a bright-red coloration was obtained when furfurol was being given off.

The methods examined may be divided into four classes, according to the degree to which inversion is carried before the removal of foreign matter from the influence of the solution. (*a*) Complete hydrolysis to glucose (as in Sachsse's method); (*b*) conversion into maltose and dextrin by ferments (Maercker's and diastase methods); (*c*) conversion to dextrins by acids (Guichard's method); (*d*) solution without chemical change (Baudry's and salicylic acid method). Most of these methods were described in an abstract on this subject in the ANALYST, xx., 17. In Baudry's method the author adopted the modification of heating for one hour on the water-bath instead of boiling.

The salicylic acid method was based on the results of experiments of Baudry's process, but had only the solvent in common with it. From one to three grammes of the finely-ground material were extracted with water, and then heated in a flask with 100 c.c. of water and 0·5 gramme of salicylic acid, in the water-bath till all the starch was rendered soluble (about 15 minutes). The liquid was filtered through muslin, the residue washed with hot water, and an aliquot part of the filtrate taken. To this one-tenth of its volume of 25 per cent. hydrochloric acid was added, and, after being heated for 45 minutes on a sand-bath under a reflux condenser, the glucose estimated in the usual manner. It was proved that in this way all the starch was made capable of being filtered before the pentosans were sensibly attacked.

In the subjoined tables, I. gives the results obtained by the different methods, and II. the results of qualitative tests for pentosans in the final solutions, the figures 1, 2, and 3 indicating the relative intensity of the positive tests. The "pure" starch sample was prepared by repeatedly washing good corn starch with dilute saline solution and water, and drying the final product in the air. It contained: ash, 0·20 per cent.; moisture, 17·36 per cent.; starch, by difference, 82·44 per cent. All the samples were ground to pass through a 60-mesh sieve, and the water-soluble matter extracted in every case before making the analysis.

I.—Percentage of Starch.

Sample.	Malt Method.	Maercker's Method.	Salicylic Acid Method.	Sachsse's Method.	Baudry's Method, modified.	Guichard's Method.
"Pure" starch	82·49	82·39	82·33	82·30	82·33	82·50
Wheat flour	66·55	67·15	66·84	68·35	...	...
Oatmeal	56·23	56·16	56·00	59·01	...	...
Graham flour	55·32	...	55·66	58·63	...	...
Wheat bran	20·97	21·07	21·57	38·82	29·74	31·36
Wheat straw	4·39	4·80	4·41	22·69	5·33	8·93
Corn fodder	0·96	...	0·92	20·13	...	...

II.—Qualitative Tests for Pentoses in Solution.

Sample.	Cold water Method.	Malt Method.	Maercker's Method.	Salicylic Acid Method.	Sacchse's Method.	Baudry's Method.	Guichard's Method.
Wheat flour ...	1	0	0	0	?	...	...
Graham flour ...	?	0	...	0	1	...	...
Wheat bran ...	0	0	?	1	3	2	2
Wheat straw ...	0	0	0	0	3	?	2
Corn fodder ...	0	0	...	0	3	...	...

From these results the author concludes that: (1) The diastase, or malt method, gives satisfactory results, and is not vitiated by any substances known to occur in cereals or grasses. (2) Maercker's and the salicylic acid methods give results fairly comparable with those of the diastase method. (3) No method based on the chemical transformation of starch by acids before removal from other substances present can be accepted as generally applicable. (4) A qualitative test for pentoses in the final solution is a valuable check in working with any of the inversion methods.

C. A. M.

The Estimation of Starch in Cereals. L. Lindet. (*Bull. Soc. Chim.*, 1896, 1163-1164.)—The various methods hitherto employed for the estimation of starch in cereals do not take into account the presence of other carbohydrates, especially sugars. Extraction of sugar with water tends to bring about the action of the diastase which is found even in non-germinated grains, whilst alcohol, though

destroying diastatic action, does not dissolve the gums (Lintner's gum, galactine, levosine). In the proposed method the author dissolves the glutinous envelope surrounding the starch by means of a solution of pepsin, and then extracts the starch by trituration and sifting. About 10 grammes of the ground grains are covered with a solution containing 1·5 c.c. of hydrochloric acid per cent. and 2 per cent. of pepsin, and the flask left for twelve or twenty-four hours, with occasional agitation, at a temperature of from 40° to 50° C. The hydrochloric acid prevents the diastase from acting on the starch without interfering with the digestion of the gluten, and the author's experiments show that under the conditions of the estimation the starch is not hydrolysed by the acid. The contents of the flask are then placed on a hair-sieve (No. 80-100), the sieve tied into a knot, and the knot enclosing the grains triturated in a basin with successive portions of water until no more starch comes through the sieve. The several starch waters are united, some corrosive sublimate or formic aldehyde added to prevent bacterial action, and the starch collected on a weighed filter. The filtration, which is tedious, may be accelerated by adding a small quantity of washed and calcined pumice-stone. The filter is dried at 50° C., and subsequently at 105° C., and weighed. The method is said to give good results with oats, wheat, and barley, as well as with malt, which always contains a certain proportion of sugar. C. A. M.

The Analysis of Commercial Glucose. J. Weiss. (*Zeit. Nahr. Untersuch.* Vienna, 1896, x., 282.)—With reference to Denamur's method of analysis (ANALYST, xxi., 194) the author considers it advisable to obtain more information as to the non-fermentable extract. In a sample described as "maltose syrup, rich in iso-maltose, he found, per 100 grammes,

Water	22·40
Extract	77·60

and in the latter:

Maltose (fermentable sugars)	46·80
Dextrin and substances fermenting with difficulty	19·80
Dextrin	10·00
Inorganic matter (ash)	0·90

C. A. M.

On the Critical Temperature of Fats and Oils. A. von Asbóth. (*Chem. Zeit.*, 1896, xx., 685, 686.)—This paper contains the results of a number of tests on pure butter and margarine which, in the main, confirm Crismer's figures (ANALYST, xx., 209 and 257). The critical temperatures obtained were 12° higher than those of Crismer, owing to the author having used an alcohol of specific gravity 0·8332 (90 per cent. by vol.). Eight samples of perfectly pure butter gave from 111·5° to 115°, while two samples of margarine gave 133° and 133·5° respectively, and a sample of oleomargarine 142°. The greatest difference between butter and oleomargarine was 30·5° (Crismer 30°), and the smallest 27° (Crismer 16°); while the greatest and smallest differences between butter and margarine were 23° and 18° C.

C. A. M.

Detection of Japan Wax in Ox-tallow. C. Dietrich. (*Phar. C. H.*; through *Zeit. Nahr. Unters.*, Vienna, 1896, x., 330, 331.)—Recently Japan wax has been considerably employed to adulterate South American ox-tallow, and to detect the addition the author recommends the following process: On warming 26 grammes of pure ox-tallow with 75 grammes of petroleum spirit, a clear golden solution is obtained, which on cooling remains completely clear, or at most deposits a few crystals. Japan wax, on the other hand, dissolves in petroleum spirit with great difficulty. With an ox-tallow which has been adulterated with Japan wax to the extent of 5 to 10 per cent., the solution, after long warming remains turbid, white, opaque, and emulsion-like; an addition of 1 per cent. caused the solution to remain opalescent.

Another simple test for Japan wax is the borax test. On boiling 0·5 gramme of the fat with 20 c.c. of a saturated solution of borax, and then cooling, the aqueous layer in the case of pure ox-tallow is completely clear and sharply separated from the fatty layer. Should, however, as little as 5 per cent. of Japan wax be present, there is neither a separation nor a clear aqueous layer, but the mass remains as a white opaque emulsion.

These reactions, in conjunction with the determination of the iodine number and critical temperature, will detect the falsification with certainty. C. A. M.

Antipyrine as a Test for Nitrites. M. C. Schuyten. (*Chem. Zeit.*, 1896. xx., 722.)—Schaack has already described a colorimetric process for the estimation of antipyrine, based on the green colour produced by nascent nitrous acid. A solution of 1 part of antipyrine in 100 of 10 per cent. acetic acid may also be employed to detect nitrites, the colour appearing rapidly even in dilutions of 1 : 20,000. The reaction is very characteristic and permanent, for the colour is only affected by oxidising agents such as ferric salts, or by hydrochloric and sulphuric acids, which turn it yellow. By the aid of a series of standard tints the test may be made quantitative; and in the examination of potable waters it should be found to possess considerable advantages over the zinc iodide and permanganate processes, as ordinary organic substances (sugar, alcohol, phenols) have no influence on the colour.

F. H. L.

Detection and Estimation of Nitrites in Water. Barbet and Jandrier (*Jour. Pharm. Chim.*, 1896, 248.)—The hydrochloride of metaphenylene-diamine, commonly used for the estimation of nitrites, has the drawback of being difficult to keep colorless. The authors describe the following method in which it is replaced by resorcin: 0·1 gramme of resorcin is dissolved in 2 c.c. of the water under examination, and 1 c.c. of pure concentrated sulphuric acid added, the acid being allowed to run down the side of the tube so as to avoid an immediate mixture. The colour is first formed at the line of juncture of the two liquids and gradually intensifies. The tube is then shaken gently, care being taken not to raise the temperature too high, and after standing for an hour the colour formed is compared with the tints obtained under precisely similar conditions with solutions containing known quantities of

sodium nitrite. Water containing 0·01 in 100,000 of nitrite of sodium gives a distinct rose coloration after standing for several hours. A colorimetric scale corresponding to the different quantities of nitrites can be established by comparing the results with a solution of cobalt chloride diluted to different strengths with distilled water.

C. A. M.

INORGANIC ANALYSIS.

Estimation of Sulphides in Calcium Carbide. F. J. Pope. (*Jour. Amer. Chem. Soc.*, 1896, xviii., 740-741.)—A weighed quantity of the carbide is placed in an Erlenmeyer flask connected with a wash-bottle containing 150 c.c. of standard lead acetate solution (about decinormal), this in turn being connected with a smaller wash-bottle. Water is carefully introduced through a stop-cock funnel into the flask until there is no further evolution of acetylene, when 25 to 40 c.c. of sulphuric acid (1 : 3) are added, and the whole boiled, the final traces of sulphuretted hydrogen being removed by means of a current of air. The contents of the wash-bottles are filtered, the filtrate made up to 100 c.c., and the amount of unconsumed lead acetate estimated volumetrically (see ANALYST, this volume, p. 269). The difference between the result and the amount of lead acetate started with gives the amount precipitated by the sulphuretted hydrogen, from which the amount of sulphur as sulphide can be calculated.

In a sample of calcium carbide the author found the following percentage of sulphur :

Calcium Carbide taken. Grammes.	Sulphur found. Per cent.
2·4492	3·37
3·1234	3·57

No check was applied to the method, and obviously, besides sulphuretted hydrogen, other substances may be evolved from impure calcium carbide which can remove lead from the solution. The author proposes to investigate the subject further.

C. A. M.

The Separation of Undissolved Phosphates in Mixed Fertilizers. A. P. Bryant. (*Jour. Amer. Chem. Soc.*, 1896, xviii., 491-498.)—Owing to their cheapness mineral phosphates have been largely employed instead of bone as a source of phosphoric acid in fertilizers. To determine the origin of the "insoluble" phosphoric acid the author has made use of the difference in specific gravity between bone and other organic matter and mineral phosphates. The specific gravities of some of the most important constituents found in bone and rock phosphates are :

	Specific Gravity.
Bone and other organic matter, less than	2·0
Gypsum	2·3
Aluminium phosphates, above	2·3
Iron phosphates, about	2·6
Silica	2·65
Calcium phosphates	2·9 to 3·55
Fluorite	3·2

For the separating solution 75 grammes of potassium iodide and 100 grammes of mercuric iodide are dissolved in 350 c.c. of water, and evaporated on the water-bath to a specific gravity of 2·26.

The apparatus required is a separating and an extraction tube. The former consists of two tubes $1\frac{3}{10}$ c.m. internal diameter, one 7 c.m. long, and closed at one end, the other 20 c.m. in length. These are connected by indiarubber tubing, so that the lower portion can be separated by a pinchcock. The extraction tube is $2\frac{1}{2}$ c.m. internal diameter, slightly contracted at one end, and with a rim over which filter-paper and cheese-cloth are tied.

Two grammes of the substance to be examined are transferred to the extraction tube, and washed with from 100 to 225 c.c. of hot water, according to whether water-soluble phosphoric acid is to be estimated or not. The tube and its contents are dried thoroughly in the water oven, and when dry the filter-paper is taken off and all matter carefully removed with a spatula and brush to the separating tube. From 15 to 20 c.c. of the separating solution are added, the tube well shaken and its sides washed down with a jet of the solution. After standing five minutes the lower part of the tube is tapped with the finger to release any light portion carried down with the heavy, whilst the matter on the top is stirred up with a jet of the solution.

The tube is left for an hour, or until the solution is clear, when the rubber connecting tube is clamped, and the lower portion removed, the fingers being protected by rubber tips. The separated portions are filtered, washed, and treated with ammonium citrate solution, and the insoluble phosphoric acid determined in the usual way. That in the "light" portion comes from bone, tankage, or other organic matter, whilst that in the "heavy" is derived from minerals. The author's experiments show that the fertilizer cannot be treated with ammonium citrate solution before separating, and that matter soluble in water must be first removed.

To test the method mixtures were made of prepared fertilizers with Florida and Carolina raw and dissolved rock, the amount of total and insoluble phosphoric acid in each being known, and the following results among others were obtained with a separating solution of specific gravity 2·26, which was found the most satisfactory strength.

PERCENTAGE OF PHOSPHORIC ACID.

The methods of analysis were those of the Association of Official Agricultural Chemists.

C. A. M.

A Method of Titrating Soluble Iodine Compounds. E. Riegler. (*Zeit anal. Chem.*, 1896, xxxv., 305-307.)—The principle of the method consists in liberating iodine from the iodides by means of iodic acid, taking up the iodine in petroleum spirit, and titrating the excess of iodic acid with decinormal thiosulphate solution. The amount of iodine is calculated from the amount of iodic acid used, $\frac{5}{6}$ of each atom of iodine being due to the decomposed iodide. The equations of the reactions are given in the following abstract. For the preparation of a decinormal solution 17·6 grammes of iodic acid are dissolved in a litre of water.

The details of the estimation are as follow: Several c.c. of the iodide solution, which must not be more concentrated than 1 per cent., are placed in a stoppered separating funnel, an equal volume of decinormal iodic acid solution added, and the funnel well shaken. After the addition of 20 c.c. of petroleum spirit, the shaking is continued until the greater part of the iodine is taken up, the remainder being removed by a fresh portion of petroleum spirit. The aqueous layer is then titrated with decinormal thiosulphate solution, starch solution being used as indicator. The difference between the amount of iodic acid taken and that left, multiplied by the factor $0{\cdot}0127 \times \frac{5}{6} = 0{\cdot}0106$, gives the iodine corresponding to the decomposed iodides. The contribution concludes with a table in which the results obtained by this method closely correspond with those required by theory. C. A. M.

Titration of Thiosulphate Solution with Iodic Acid. E. Riegler. (*Zeit. anal. Chem.*, 1896, xxxv., 308.)—The reaction on which this is based is

$$6Na_2S_2O_3 + 6HIO_3 = 3Na_2S_4O_6 + 5NaIO_3 + NaI + 3H_2O.$$

For the indicator starch solution is added to the thiosulphate solution. As soon as the reaction is complete, the slightest excess of iodic acid sets free iodine, which is shown by the blue colour given to the starch.

$$5NaI + 6HIO_3 = 5NaIO_3 + 3H_2O + 6I.$$

Iodic acid is readily obtained in a state of purity; the crystals are not hygroscopic, and its aqueous solutions do not readily undergo change. In preparing the solutions for standardizing thiosulphate solution the pure crystallized acid is first dried over sulphuric acid. C. A. M.

LEGAL.

IMPORTANT DECISION WITH REFERENCE TO BEESWAX.

QUEEN'S BENCH DIVISION.

(*Before* MR. JUSTICE GRANTHAM *and* MR. JUSTICE WRIGHT.)

FOWLE *v.* FOWLE.

(*Reprinted from the "Pharmaceutical Journal" of November 7, 1896.*)

IN the Queen's Bench Division on November 2, before Mr. Justice Grantham and Mr. Justice Wright, the case of *Fowle* v. *Fowle* came before the Divisional Court, on a special case stated by the magistrates sitting at Cranbrook, in Kent, the appellant being the Inspector under the Sale of Food and Drugs Act, and the respondent a grocer at Marden. Mr. T. Mathew appeared for the appellant, but the respondent was not represented. The facts, as stated in the special case, were as follows: A man named Skinner, sent by the Inspector, went into respondent's shop and asked for a quarter of a pound of beeswax, which the respondent thereupon supplied.

Skinner asked if it was pure, and respondent said he could not guarantee it. Skinner said, "But you sell it as beeswax?" and the reply was, "Yes." Skinner thereupon took it away, and on being analysed it was found to contain 50 per cent. of paraffin. Definitions from Chambers' "Etymological Dictionary," and "The Lexicon of Applied Science," went to show that a drug was anything used in medicine, or any medicinal substance either used in its natural condition or prepared by art, or mixed with other substances to form a medicament or medicine; and the British Pharmacopœia was referred to as showing that yellow wax was used in the preparation of certain medicines, no less than twenty being mentioned, especially phosphorus pills. It was admitted that to obtain the wax mentioned in the British Pharmacopœia beeswax was melted, and certain impurities taken out. It was also said that the properties of this prepared wax, when used with oil, were of a healing and emollient character, and that it was used by chemists and druggists. A witness, who was a chemist (the name not being mentioned), was unable to say what was the medicinal or healing effect of beeswax alone, nor had he ever known it used alone. He described it as being used as a vehicle only, but in his opinion there was no manner of doubt as to its being a drug. On these facts it was contended by the appellant that it was a drug and by the respondent that it was not, and in any case that it was not the sale of a drug to the prejudice of the purchaser. The justices found: 1. That prepared beeswax, known as yellow wax, with the allied preparation known as white wax, is a substance mentioned in the British Pharmacopœia, and used in the preparation of medicines. 2. That wax used in the preparation of medicines is used as a vehicle only, and not as possessing any healing or medicinal properties, and that the sale of beeswax in this case was not in their opinion to the prejudice of the purchaser, because of the statement made by the respondent to Skinner. 3. That the sale of the said beeswax was a sale by the respondent as a grocer. On these facts they held that the beeswax in this case was not a drug within the meaning of the Act; and, further, that if it were, the said sale was not to the prejudice of the purchaser, nor was the sale by the respondent as a grocer a sale of a drug within the meaning of the Act.

Mr. JUSTICE GRANTHAM said there was no suggestion of any fraud here. The respondent kept a grocer's shop in a small place, and sold a variety of things, amongst them this beeswax. He did not know whether it was pure or not, and said so; it was probably a cheaper article than some of the finer qualities. He got that which was generally used, the constituents of which were paraffin and beeswax, which was probably more useful for some purposes than if it were pure wax. There was nothing improper in it, and he said he could not guarantee its being pure. It was very hard to say that the man should be punished because it turned out there was paraffin in it.

Mr. MATHEW suggested that the grocer would know that beeswax was a thing commonly used in medicinal preparations.

Mr. JUSTICE GRANTHAM thought it was about the last thing he would know about it.

Mr. MATHEW submitted that, though he might be allowed to sell it with its natural impurities, he could not be entitled to add to it a foreign substance which might be deleterious when used in medicine.

Mr. JUSTICE GRANTHAM said there was no suggestion that he added the paraffin himself; he had not the slightest doubt that he bought it as it was.

Mr. MATHEW went on to contend at some length that the beeswax in question must be considered the same as the yellow wax mentioned in the Pharmacopœia, which was used in making various medicinal preparations, and to point out the evil consequence which might ensue if a chemist purchased any of this wax from the respondent for use in the preparation, say, of phosphorus pills.

Mr. JUSTICE GRANTHAM said such a chemist ought to be fined very heavily for buying any drug from a small grocer in a little country town.

Mr. MATHEW suggested there would be no negligence if he believed it to be the proper article.

Mr. JUSTICE GRANTHAM said it would be worse than negligence; it would be guilty knowledge. A chemist ought not to buy drugs from a grocer.

Mr. MATHEW, continuing, said the grocer ought to tell the purchaser that it contained paraffin.

Mr. JUSTICE GRANTHAM said the grocer did not know what it contained.

Mr. MATHEW suggested that, if the justices were right in this case, it would be perfectly possible for a chemist dealing with yellow wax to adulterate it and sell it in the same way.

Mr. JUSTICE GRANTHAM said when such a case came before the Court they would deal with it.

Mr. MATHEW continued for some time longer to urge that beeswax was the same as yellow wax, and was a drug as being used in medicine, and cited several other dictionaries and cyclopædias.

Mr. JUSTICE WRIGHT asked whether bread, which was often used medicinally in the form of a poultice, was a drug.

Mr. MATHEW said he should contend, if it were mentioned in the Pharmacopœia, that it would be.

Mr. JUSTICE GRANTHAM suggested that Quaker oats would also come within the definition, and also water, which entered into most fluid mixtures.

Mr. JUSTICE WRIGHT also put the case of wine and brandy.

Mr. MATHEW said they were clearly not drugs, but anyone who adulterated wine would be liable under the term "food or drink." He continued the argument for some time longer, and cited various cases, one of which was with regard to the sale of saffron.

Mr. JUSTICE GRANTHAM, in giving judgment, said as no one appeared on behalf of the respondent in this case, the Court had not had the benefit of the argument which would have been used by counsel on his side, but it was the duty of the Court to watch carefully the interest of a person not represented, and make such suggestions as occurred to them, whether for or against the argument presented by the appellant. It certainly struck both his learned brother and himself that there were a great many difficulties in his way, and they had come to the conclusion that it was not desirable to interfere with the decision of the magistrates in this case, but that it was the right decision. In the first place, speaking for himself, he was not prepared to admit that beeswax was a drug when sold as it was by a grocer in a country shop, and not sold as a drug by him. It might be possible by straining a point, and going into all the pharmacopœias and dictionaries that could be found, that in one or more of them you might find such a definition as would bring this within it, but it was quite clear from most of the definitions read by the learned counsel that this would not come within it, although it might in some others. He thought the magistrates were right in referring to the fact that this was sold by a grocer; everyone could no doubt think of instances in which beeswax was used not as a drug. The primary use of beeswax used to be to polish mahogany tables, and you might use a drug for that purpose; but that was not a medicinal purpose, except so far as it would act medicinally for the benefit of the person polishing the table using a great deal of elbow grease, which would be a very healthful occupation. Not to give other instances in which beeswax was used which were certainly not medicinal, he should think not one grocer in a thousand ever used beeswax as a drug; he sold it for the ordinary purposes of trade. As he had said before, if a doctor were to buy beeswax as a medicine he would not go to the ordinary country grocer and buy the cheap beeswax which was sold there; it would be very culpable and negligent on his part if he did. The magistrates had to deal with the facts as they were and people as they found them, and the knowledge they had of the kind of trade they did. It seemed to have been assumed, on behalf of the appellant, that the grocer made his beeswax, but that was not

so; he bought it. He was asked if it was pure; he said, "I do not know; I cannot tell you that it is pure; it is what we sell; we have to sell beeswax; but I do not know what its constituents are." Thereupon the man bought it, and it would be very hard indeed after that if he were to come and say, because there was some other substance in it, he was to be fined. Under these circumstances he thought the magistrates were quite right in dismissing the application.

Mr. JUSTICE WRIGHT said he was of the same opinion, on the ground that it must be in many cases a question of fact whether a particular thing was a food or a drug or something else, which the magistrates must determine in each case. In this case he thought they had rightly determined. Take, for instance, turpentine. Turpentine, if sold to be used by a carpenter, ought not to be held to be a drug for the purpose of this Act, or resin. He supposed both turpentine and resin were used in medicine, and if sold by a chemist to be used in medicine it would be a drug; but if resin were sold to be used by a musician he should say it was not a drug. Another point which seemed to him much more important, whether the mere fact of the seller saying that he could not guarantee the article to be pure would prevent it being to the prejudice of the purchaser, he would rather not decide at present; but certainly the case cited was a very different one from the present.

REVIEW.

APPLIED BACTERIOLOGY. By T. H. PEARMAIN and C. G. MOOR. (London: Baillière, Tindall and Cox.) Price 12s. 6d. net.

This work, which is primarily intended as a handbook for students and medical practitioners, contains much that will be found of great practical value to the analyst, who is now so frequently called upon to undertake bacteriological investigations. In order to keep the book within the limits of a handy size, the authors have endeavoured to select from the vast mass of material at their disposal only those portions the results of which have been established, or are likely to be so in the near future. The practical portion of the work, as might be expected from the wide experience of the authors, has been exceptionally well done. In the chapter referring to the "Methods of the spread of infection," the subject has been treated in a somewhat novel and ingenious manner. An elaborate description is given of the bacterial organisms which are the cause of the more commonly occurring infectious diseases of man, with the special methods for their individual identification. This is followed by a brief description of the principal yeasts and mould-fungi, and of the more commonly-occurring enzymes, together with their fermentative actions. Next comes a chapter on ptomaines and on the biological testing of disinfectants, followed by another on the examination of water, filters, air, and soil, to which is appended a succinct description of a number of micro-organisms not mentioned in the preceding pages. Steam sterilizers are separately treated of in the appendix. The work is well printed and illustrated, and especial reference must be made to the beautifully-executed colored plates representing the bacteria and the manner of their growth when cultivated under different conditions. We congratulate the authors on the production of a really useful book, eminently adapted for the wants of those who, like analysts, only require the essence of the subject given in a lucid and terse form. W. J. S.

THE ANALYST.

FEBRUARY, 1897.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE annual general meeting was held on Wednesday, January 13, 1897, in the Chemical Society's Rooms, Burlington House, the President (Dr. Stevenson) occupying the chair.

The minutes of the previous meeting were read and confirmed.

In the absence, through illness, of the Hon. Treasurer (Mr. E. W. Voelcker), his report and the accounts for the past year were presented by Dr. J. Augustus Voelcker, and, on the proposal of Mr. Archbutt, seconded by Mr. Ekins, were unanimously adopted.

Mr. Archbutt and Mr. Budden were appointed to act as scrutators of the ballot-papers.

It was proposed by Mr. Smetham, and seconded by Mr. Page, that a vote of thanks should be accorded to the Hon. Treasurer and Hon. Auditors for their services during the past year. The motion was carried unanimously.

The following gentlemen were nominated by the Council for election as Associates: Mr. Arthur Angell, jun., assistant to Mr. Arthur Angell, Southampton; Mr. W. H. Jackson, assistant to Mr. A. C. Wilson, Stockton-on-Tees; and Mr. Arnold Rowsby Tankard, assistant to Mr. Alfred H. Allen.

Mr. Frank H. Stephens was elected a member.

The PRESIDENT then delivered the following address:

THE PRESIDENT'S ANNUAL ADDRESS.

The past year has been one marked in the annals of the Society by quiet, steady progress, and some important events to which I shall presently refer in detail.

During the year we have elected 1 Honorary Member and 11 new ordinary Members, also 6 Associates, and 1 Associate has been transferred from the list of Associates to that of Members. On the other hand, 1 Member and 1 Associate have resigned, and the names of 2 Members and of 1 Associate have been removed from the list for non-payment of subscriptions. The respective numbers of the Members and Associates as compared with those of the previous year are therefore as follows:

	January, 1896.	January, 1897.
Hon. members	10	11
Members	210	218
Associates	26	29
Total	246	258

The following papers were presented to the Society:

"Note on a series of Analyses of a Private Water Supply." By E. Russell Budden.
"The Determination of Oxygen in Commercial Copper." By Bertram Blount.
"The Composition of Milk and Milk Products." By H. Droop Richmond.
"A new form of Carbonic Acid Apparatus." By Cecil H. Cribb, B.Sc.
"Laboratory Notes." By Alfred H. Allen.
"On the Estimation of the Diastatic Power of Malt." By Walter J. Sykes, M.D., and C. A. Mitchell, B.A.
"Further Note on the Detection of Formalin." By H. Droop Richmond and L. K. Boseley.
"The Detection of Formalin." By Otto Hehner.
"Note on the Detection of Cotton-seed Oil in Lard." By E. J. Bevan.
"The Bacteriological Examination of Water for the Typhoid Bacillus." By T. H. Pearmain and C. G. Moor, M.A.
"Note on the Estimation of Formic Aldehyde." By Harry M. Smith.
"Note on Hehner's Test for Formic Aldehyde." By Norman Leonard, B.Sc.
"The Composition of Human Fat." By C. A. Mitchell, B.A.
"Note on an Incrustation found in Hot-water Pipes." By J. Augustus Voelcker, M.A., B.Sc., Ph.D.
"The Examination of Commercial Milk Sugar." By H. Droop Richmond.
"Note on 'drawn' or exhausted Caraways." By Bernard Dyer, D.Sc., and J. F. H. Gilbard.
"The Analysis of Mortar." By W. J. Dibdin and R. Grimwood.
"Commercial Prussian Blue." By Ernest J. Parry, B.Sc., and John Henry Coste.
"Commercial Cream of Tartar." By Alfred H. Allen.
"Note on Lead in a Sample of Canadian Cheese." By F. Wallis Stoddart.
"Note on Ginger." By Thos. P. Blunt.
"The Determination of Stearic Acid in Fats." By Otto Hehner and C. A. Mitchell, B.A.
"Further Note on Lead in Canadian Cheese." By F. Wallis Stoddart.
"Note on Formalin." By Samuel Rideal, D.Sc., and Ronald Orchard.
"On the Separation and Estimation of Formic Aldehyde." By Norman Leonard, B.Sc., and Harry M. Smith.
"Notes on Prussian Blue." By Frank H. Leeds.
"The Estimation of Borax and Boracic Acid in Milk." By Frank P. Perkins.
"Note on Copper in Oysters." By W. F. Lowe.
"The Statement of Analytical Results." By J. F. Liverseege.

The papers read before the Society—twenty-nine in number—have as a rule not presented any such marked characteristics as to render them landmarks of great advances, with the exception of that on "The Determination of Stearic Acid in Fats" by Messrs. Hehner and Mitchell. This paper, indeed, is eminently suggestive, and

promises an entire reconstruction of our existing and too imperfect methods of analysing fats.

I trust that our members appreciate the improved and extended form in which our organ, the ANALYST, has appeared during the year that has just passed. Under the able editorship of Dr. Sykes, and under the direction of the Publishing Committee —where the attendance has been regular and good, and the criticisms and discussions careful and valuable—the ANALYST has made a distinct advance. It is now the only journal for analysts appearing in this country worthy of the name. In it, besides the original articles above named, there have appeared in abstract the following number of papers:

Food and Drug Analysis	55
Toxicological Analysis	9
Organic Analysis	91
Inorganic Analysis	86
Apparatus	9
	250

In the early months of the year 1896 the judgment in a Divisional Court, Queen's Bench Division, of Hawkins J. and Kennedy J., in the case of Fortune *v.* Hanson, as to the insufficiency of a certificate relative to milk, engaged the attention of your Council. After mature deliberation and with excellent legal help, a circular was issued on April 11 last expressing the views of the Council as to the forms of certificate that should be used in the cases of watered milk and watered butter respectively. Some magistrates refused to accept our amended form of certificate relative to milk. But a Divisional Court of the Queen's Bench Division, by the judgment of Grantham J. and Kennedy J. in the case of Bridge *v.* Howard, affirmed the sufficiency of our form of certificate, which will now I hope be generally adopted as explicit, safe, and sufficient. This judgment is the more satisfactory as one of the two judges giving it was also one of the judges who decided the previous case of Fortune *v.* Hanson.

By far the most momentous event of the year has been the issue of the Report of the Food Products Adulteration Committee, a committee which, fortunately, was able to bring to a close its protracted sittings in time for its report to be presented to the House of Commons before the prorogation of Parliament. Our distinguished Past President, Mr. Hehner—and, I may add, on the special request of your President. and I am sure with your approval—most ably and vigorously gave clear, emphatic, and impartial evidence before the committee, and obviously deeply impressed it. Indeed, he proved himself as skilful a Field-officer as we had previously known him to be a General of consummate tact and ability. Again, in the name of the Society, let me tender him our warmest thanks for all that he has done to advance the views of the Society and the aims of our best public analysts. In my further remarks I have to acknowledge the assistance he has so generously afforded me in dissecting the recommendations of the committee.

The report of the committee has two very distinct aspects. If the "Summary of Principal Recommendations," set out on page 41 of the report, is alone read by anyone not having the patience to wade through the whole report, the impression

gained would be unfavourable to the views of our Society, and an insufficient and incorrect view would be obtained of the gist of the report, for there is a strange discrepancy between the report itself and the summary of its principal recommendations. Indeed, in the summary many of the things of real importance recommended by the committee in the body of the report are either so inadequately stated or omitted that, if the summary alone is looked at, it would appear that the committee desired to make the proposed Act worse from the public analysts' point of view than the existing Act. A careful perusal of the body of the report will, however, convince the reader that the report is written in a much juster spirit than would appear from the summary. In the first place, the committee state that the existing Acts, where well administered, have had most beneficial results, and that the better they have been worked the more adulteration has declined. In accordance with our draft Bill, the committee emphasise the necessity of having at least one sample analysed annually per 1,000 inhabitants of a district; but the committee were evidently not familiar with the Sale of Food and Drugs Acts, for they recommended that the County Councils should force the local authorities to carry out the Acts, apparently forgetful of this—that the County Council is itself the local authority, and has no jurisdiction, *quâ* the Acts in question, to compel local authorities to procure samples and have them analysed.

As to the giving of notice by the vendor to a purchaser that an article is mixed, it is recommended that for a verbal notice an obligatory and legible labelling of the mixture should be adopted. This is in accordance with our recommendation, except that the report does not go the length of advising that the proportions of the respective ingredients of a mixture, or even that the nature of the components, be required to be stated. Doubtless it was thought by the committee that it was not desirable to enforce the disclosure of trade secrets, and that an attempt to do this would be inoperative.

The recommendation as to warranties is practically that advised by our Society, though, if the summary only be consulted, an inadequate impression of the far-reaching character of the intended use of warranties would be obtained. Invoices are to have the force of warranties so far as the retailer is concerned; but only on conditions—the incidence of the prosecution is to be transferred to the wholesale dealer.

As to the examination of imports by the Customs, the intention of the committee is good; but as the committee is against the stoppage in transit of articles found adulterated, the proposed examination by the Customs will probably be without result. The inspectors ought to be empowered to take the article without delay to the local public analyst, and should be empowered to take proceedings on his certificate, instead of incurring the delay involved in the reference to a central public laboratory.

Importers are to submit guarantees of the purity of their food imports to the scrutiny of the Customs; these guarantees to be given by the foreign vendors, together with evidence that the importers have taken proper measures to see that the goods are such as they are guaranteed to be. The excuse of ignorance will thus be removed.

And in this connection I may refer with satisfaction to the recent conviction of a wholesale firm of English dealers in lard, for the sale, under a false name, of lard

containing 10 per cent. of beef-stearin, but guaranteed as pure refined lard. This conviction has not been appealed against, and I hope it will greatly tend to the stoppage of the sale of such articles under a misleading title. No imputation, except of carelessness, was made against the wholesale dealer, who was not the manufacturer of the lard; nevertheless he was convicted.

The recommendation, in accordance with the expressed views of this Society, that the present provision as to samples of milk being taken for analysis in transit should be extended to all articles is satisfactory.

The contemplated provision for a purchased sample being divided into four parts, one of which is to be at the disposal of the wholesale dealer, is theoretically a most just and equitable recommendation. It, however, if adopted, will greatly increase the difficulties of administration. Many articles are costly, and the purchase of unusually large quantities in order to have sufficient for four independent analyses, will excite suspicion as to the intention of the purchaser. In the case of tinned articles, the further recommendation that a retailer shall be empowered to refuse to sell an article otherwise than in a manufacturer's unopened labelled tin or packet, increases the difficulty. No exception can be taken to the recommendations that all certificates, whether of a public or Government analyst, must be given within twenty-eight days, and that magistrates may not refuse a reference analysis to Somerset House.

But the recommendation that the certificate of a public analyst employed by the defence should be received on equal terms with that of the certifying public analyst whose certificate is in question is a very doubtful proposed innovation. Happily, the certificate of anyone not a public analyst is not admissible, and the care to be exercised in the determination of the qualifications of a public analyst to be hereafter demanded, remove some of the objections to the departure from existing use. It will, however, behove a public analyst, when receiving unknown samples, to take care that he is not imposed upon to the detriment of one of his official professional brethren, and it will be incumbent on our Society to strictly watch the conduct of public analysts in this regard.

In one respect the report goes beyond the recommendations of this Society, made in its Draft Bill. Penalties for adulteration are to be increased. It will be remembered that the reason why this Society did not make this recommendation was that penalties were considered to be outside the province of public analysts.

Very important and welcome are the proposals as to a more stringent and specific test of the qualifications of a candidate for the post of public analyst being prescribed, coupled with the statement of the committee that hitherto the duties of the office have usually been discharged with commendable efficiency, and the advice that remuneration by way of both stipend and fees is best calculated to secure the services of the most competent analysts. It is also proposed to make his remuneration subject to the approval of the Local Government Board.

The proposed extension of the definition of the word "food" as used in the Acts, so as to make it include expressly all articles intended to enter into or be used in the preparation or flavouring of food, is a welcome extension of the law; and it is to be hoped that if adopted by the Legislature it will put an end to the sale of presumptively noxious, though not actually poisonous, baking powders and the like articles.

But this leads up to the most important of all parts of the report—the adoption by the committee of the principle of the establishment of a Scientific Court of Reference under the Board of Trade, and independent of the Government Laboratory. This recommendation, and the admission of the necessity for it, met with much opposition; but the able advocacy of Mr. Hehner was irresistible. The words of the committee are clear and emphatic as to the necessity for such a reference tribunal. After referring to the absence of food-standards, or precise definitions of the composition of articles of food to which the Act is understood as referring, and which the purchaser is presumed to have in mind when making a purchase, they say that the article demanded must be supposed to mean an article of the nature, substance, and quality of the article usually sold under that name, and as to the variation of the composition of many articles of food sold under one and the same name, they add that there is a substantial reason for dissatisfaction with the existing provisions of the law upon this subject, and the decisions by tribunals seldom in possession of sufficient data for the satisfactory decision of such questions. Hence they point out how the working of the law as to the adulteration of food would be facilitated, and the interests of traders served, if standards or definitions of foods were promulgated by competent authority. This cardinal principle, for many years advocated by this Society, has thus received its due recognition, and there can be no doubt that when a Bill is introduced by the Government this provision for a Court of Reference must form part of its provisions, and, in the words of the committee, the Reference Tribunal must be a specially constituted scientific body, familiar with questions of analysis and the chemistry of food. All this I heartily endorse.

But as to the Court of Reference, the committee do not give us in their recommendations all that we asked for, or all that justice demands. We are not to be directly represented in that body. Who are so familiar with foods, their composition and analysis, as the members of our own body, which embraces practising analysts of the highest distinction in every department of food and drug analysis? What body of men in this empire has more advanced scientific analysis than our Society? What British Journal more teems with original analytical research than ours? The Chemical Society has practically long ceased to take interest in analytical work, except as to the means of determining formulæ; the Pharmaceutical Society only advances analysis in a limited field; and the Institute of Chemistry is an examining and qualifying body only. The Society of Public Analysts has now for a quarter of a century been the pioneer of analytical progress in this country. The result of the committee's deliberations is a compromise. An unworthy proposal to exclude public analysts altogether from the Court of Reference was, however, happily rectified. There is no doubt that public analysts will sit in the Court of Reference, which would be an incomplete and incompetent court without them. The Institute of Chemistry and its Council contain so many able and prominent chemists who are also public analysts, that there is little doubt that the apparent unfairness of the exclusion of public analysts from a seat on the proposed Board will be rectified unless, by some strange fatality, the members of the Institute of Chemistry, which is to be represented, be also excluded from the provisions of the forthcoming Bill. But that contingency is not likely to occur. For my part, I

think that it is immaterial how the members of the court are selected, provided that competent persons be secured whose decisions will command respect. Did I think the "analysts of repute," among whom the representative of the Institute of Chemistry finds a place, would not include public analysts, I, for my part, would vigorously protest against the finding of the committee; but I think we may congratulate ourselves on having gained, though indirectly, all that we demanded as to a Court of Reference.

It is a matter for satisfaction also that the unwillingness of the officers of the Government Laboratory to communicate information to the Society of Public Analysts, lest we should think such action to be dictation, is gently, but firmly rebuked, when the committee state that they regard it as of great importance, in the interests of the public, that public analysts should, as far as possible, be made acquainted with the methods adopted by the Government Laboratory in the analysis of food, and with the considerations kept in view by them in determining whether an article has been adulterated. Doubtless we may expect this emphatic pronouncement to have a generous and not tardy response, and the official book, which ought to be, and possibly is, in course of preparation by Somerset House, placing all the analytical methods used in food and drug analysis, and the deductions that ought to be drawn from the results of analysis at our disposal, will be welcomed by public analysts as a priceless boon.

The report of the committee may be considered as, on the whole, a recognition of the principles advocated by this Society, a testimony to our usefulness, and of the ability and discretion with which public analysts have discharged their duties, of the fewness of the errors committed by us, and an admonition to the Government analysts to be less grudging of information than of yore. Nearly every vital point advocated by us has been gained.

The committee, indeed, in its report and recommendations, though of course it has not endorsed all the views put forth by the Society in its Draft Bill so well known to us—has substantially adopted most of our recommendations.

That portion of the report which deals with specific articles, such as coffee and cocoa, is of less importance, seeing that the Board of Reference will manifestly have to determine the composition of all such articles and their legitimate mixtures.

The invaluable aid rendered to the Society by Mr. Kearley, M.P., with reference to contemplated new legislation, received the only recognition which this Society could bestow, by his being unanimously elected an honorary member of the Society.

There can be little doubt that the Government ought to feel it incumbent on them to introduce into Parliament a Bill, based on the report of the committee, at an early date, and it is devoutly to be wished that the Bill may not be crowded out by a plethora of less important matters. Traders, public authorities, and public analysts are all desirous that a Bill may not be delayed, and that it may speedily be enrolled in the Statute Book.

Let me congratulate the Society on what it has done to forward these matters.

Mr. CASSAL said that he had great pleasure in rising to propose that the Society should tender to Dr. Stevenson its cordial thanks for his valuable services as

President during the past year, and for the admirable address to which they had just listened. He was sure that all who had had the opportunity of sitting under Dr. Stevenson's guidance at the Council-board of the Society, and all who had been in the habit of attending the meetings so genially presided over by him, would agree that Dr. Stevenson had been essentially the right man in the right place. He had been an admirable leader of the Society and of the profession during two momentous years, perhaps the two most momentous years in the existence of the Society since the passing of the Sale of Food and Drugs Act in 1875. He (Mr. Cassal) ventured to think that Dr. Stevenson had worthily filled the chair, and had ably supported a policy which, without being charged with invidiousness, the speaker thought he might say had been initiated by Mr. Hehner when President of the Society. He (Mr. Cassal) would have liked to enlarge at greater length upon all that the Society owed to Dr. Stevenson; but the annual dinner was looming in the very immediate future, and he would therefore now ask the meeting to express the Society's thanks to Dr. Stevenson for the services which he had rendered to it, and to wish him in his retirement all prosperity and happiness.

Mr. W. F. Keating Stock had much pleasure in seconding the motion, which, on being put to the meeting by Mr. Cassal, was carried unanimously amidst loud applause.

Dr. Stevenson said he desired to thank the meeting heartily for the vote which had been passed to him in such a cordial manner. It had been a very great pleasure to him to preside over the Society. He was glad to think that he had been able to conduct the affairs of the Society amicably during his term of office, and, he trusted, successfully. He was glad to be able in his address to congratulate the Society upon its success in securing the report which had been made by the Select Committee on Food Products Adulteration, and the carrying out of the policy which, as Mr. Cassal had justly said, was so greatly contributed to by Mr. Hehner. In laying down the cares of office and going into retirement, he did not intend, as Mr. Cassal seemed to intimate, to absent himself in future from the meetings. His attendance might not perhaps be so constant as it had been during the past two years, but he hoped to be with the Society very frequently, and to retain his interest and influence in its proceedings.

The following papers were read:

"A Specific Gravity Pipette." By W. F. Keating Stock.

"Note on Weighing out Fats." By Charles E. Cassal.

"A Modified Schmidt Process." By R. W. Woosnam.

The scrutators reported that the list of Officers and Council elected for 1897 was as follows:

President.—Bernard Dyer, D.Sc.

Vice-Presidents (who have filled the office of President).—M. A. Adams, F.R.C.S.; A. H. Allen; Sir Chas. A. Cameron, M.D., F.R.C.S.; A. Dupré, Ph.D., F.R.S.; Otto Hehner; Alfred Hill, M.D., F.R.S.E.; J. Muter, M.A., Ph.D., F.R.S.E.; Thos. Stevenson, M.D., F.R.C.P. (Who have not filled the office of President)—W. P. Aitken, D.Sc., F.R.S.E.; W. W. Fisher, M.A.; John Pattinson.

Hon. Treasurer.—E. W. Voelcker, A.R.S.M.

Hon. Secretaries.—E. J. Bevan, Charles E. Cassal.

Other Members of Council.—Leonard Archbutt, Bertram Blount, A. Wynter Blyth, M.R.C.S., R. Bodmer, E. Russell Budden, A. C. Chapman, W. J. Dibdin, Sidney Harvey, S. Rideal, D.Sc., Alfred Smetham, J. E. Stead, John A. Voelcker, M.A., B.Sc., Ph.D.

The annual dinner subsequently took place at the Criterion Restaurant.

THE USE OF ANTISEPTICS IN FOOD.

(*Abstract of Report of the "Lancet" Special Commission.*—"*Lancet*," 1897; p. 56.)

THE Select Committee appointed by the House of Commons on Food Products Adulteration did not offer a pronouncement on the question of antiseptics in food, but expressed themselves as follows: "Your committee think that the matter is one which deserves further investigation by recognised scientific authorities, with the view to the expression of an opinion that would be regarded as authoritative." In another section of their report they mentioned the legitimacy of the use of preservatives as a subject for consideration by the proposed Court of Reference.

It being obvious that an authoritative expression of opinion must rest on the evidence and experience of medical men of recognised authority, the Editors of the *Lancet* addressed a letter to several leading members of the profession, containing the following questions:

(1) "Is the presence of small quantities of salicylic, boric, or benzoic acids, or 'formalin' in food, in sufficient quantities to preserve it, injurious to health?"

(2) "Should the use of antiseptics for this purpose be forbidden by law altogether?"

(3) "Should legislation be brought to bear on the restriction of the amount?"

(4) "Should the law insist that when preservatives are used the fact should be stated on the label?"

In answer:

Sir HENRY THOMPSON wrote that "he had long held that the addition of antiseptics was undesirable, though unable to produce evidence that any one of them had given rise to deleterious action, owing to the impossibility of isolating the precise influence of the drug. He objects strongly to the *dietetic* use of drugs, and is of opinion that the name and quantity of the antiseptic employed should be on the label, or on a paper setting forth the maker's or vendor's name."

Dr. PAVY wrote that "he did not consider our knowledge sufficiently extended to permit of its being taken for granted that no injury is producible, though there is no evidence of injury to health. He points out that it is the vendor, and not the consumer, that is benefited. He considers that notification of the fact of antiseptics being employed, and their nature and amount, would be sufficient; any deviation from the notification should be liable to prosecution. With the public interest thus

safeguarded, he thinks that advantage might be taken of the power of antiseptics in preserving articles of food."

Dr. F. J. ALLEN points out the possibility of daily accumulation of antiseptics quite sufficient to produce a gradual lowering of the standard of health, and is of opinion that the fact of an antiseptic being added, and its nature, should be required by law to be announced at the time of sale.

Dr. SIMS WOODHEAD draws attention to idiosyncrasy and cumulative effect, and dwells upon our ignorance of the action of certain drugs (*e.g.*, formalin) on food stuffs. He points out that by the use of preservatives foods of inferior quality may be "doctored." He would make the use of antiseptics illegal unless their nature and quantity be made known.

The late Sir B. W. RICHARDSON considered that antiseptics are not only necessary at this moment, but when used in proper form and quantity, cause no injury whatever. There ought to be a license given permitting a certain fixed, and not a dangerous, quantity of antiseptic, and it ought to be stated on the label what the antiseptic is and its quantity.

Dr. T. LAUDER BRUNTON writes that "one must remember that poisons are formed in foods by spontaneous decomposition, which may take place after purchase. The question to be decided comes to be whether antiseptics are likely to be more injurious to health than the natural products of decomposition. His own belief is that preservatives are the less injurious. His answers are: (1) The use of antiseptics should not be forbidden by law. (2) It is doubtful whether legislation should restrict the amount, as the makers will probably use the minimum amount found sufficient. (3) The fact of preservatives being used, and their amount, should be stated on the label."

Sir W. ROBERTS says that "there is no reliable information available, and an inquiry is needed."

Dr. W. D. HALLIBURTON is not able to give information as to injurious effects from his experience, but quotes F. J. Allen as mentioning cases of ill-health in children due to boric acid.

Dr. J. B. BRADBURY thinks that "it is not necessary to forbid antiseptics, but that the amount should either be restricted, or the fact of their addition stated on the label."

Dr. WHITELEGGE cannot speak positively, though it is clear to him that the law should insist upon a plain statement on the label if any preservative be added.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Modifications in the Composition of Brandies through Age. X. Rocques. (*Ann. de Chimie Analyt.*, vol. i. [20], pp. 385-389.)—The conclusions deduced by the author from his researches are to the effect that the co-efficient of impurities—volatile substances other than ethyl alcohol—increases considerably with age; the proportion

of oxidation products (acids and aldehydes) is also largely increased; the proportionate increase of the higher alcohols and ethers is much smaller, and only relative, being chiefly due to concentration; the ratio of the higher alcohols to the ethers is larger; and the total quantity of volatile substances, apart from ethyl alcohol, is about the same in *corresponding* volumes of new and matured brandy, the gain in oxidation products compensating the loss in ethers and higher alcohols. C. S.

Estimation of Salicylic Acid, and its Detection in Wine, Beer, etc. F. Freyer. (*Chem. Zeit.*, 1896, xx., 820.)—This paper consists chiefly of a description of the tribromophenol method of determining salicylic acid; and, provided that at least twice as much of the bromine is present as is required in the reaction, the author finds that it is possible to obtain satisfactory results, except in the case of wine and beer (as has already been pointed out by Elion).

The process for the detection of salicylic acid in the latter liquids is based on its volatility in presence of steam, and its colour reaction with ferric chloride. Fifty or 100 c.c. of the sample are distilled until two-thirds have passed over; the receiver is changed and the process continued till only 5 c.c. are left in the retort. A trace of ferric chloride is then added to the second distillate, preferably by stirring it with a rod moistened with a dilute solution, and any red coloration noted. The method is available if the wine contain not less than 0·02 gramme of salicylic acid per litre; it avoids the tedious extraction with ether, etc. (*cf.* ANALYST, xx., 184), and it has the additional advantage of enabling the alcohol in the liquid to be also determined at one operation (in the first distillate). Should a smaller percentage of the preservative be suspected, the ordinary treatment with petroleum ether must be carried out, as this will detect 0·01 gramme per litre (*cf.* Spicer, *loc. cit.*).

The author has been unable to check the process on those wines that, as Medicus has observed, naturally give a petroleum ether extract coloured violet with ferric chloride; but as this reaction is only obtained when at least 100 c.c. are used, perhaps not more than 50 c.c. of the sample should be taken in testing for salicylic acid.

F. H. L.

The Effect of Coal-Tar Colours on the Process of Digestion. H. A. Weber. (*Amer. Chem. Jour.*, 1896, xviii., 1092-1096.)—Experiments on lower animals have led to the belief that most of the coal-tar colours used for confectionery purposes are quite harmless; but as there was no published account as to their influence on digestion, the author has tested some of those most commonly employed.

The ferments used were Armour's pepsin and pancreatin, and the substance to be digested, blood fibrin. In each experiment on peptic digestion a mixture composed of hydrochloric acid solution ($\frac{2}{10}$ per cent.), 100 c.c.; pepsin, 20 milligrammes; and fibrin, 1 gramme, was digested in the water-bath at 38°-40°, while in a similar series of tubes weighed quantities of the colour were added. Any fibrin remaining undissolved after the time required to dissolve that in the control tube was removed, washed, pressed between filter-paper, and weighed.

Pepsin and Oroline Yellow.—This colour, known in the trade as *acid yellow* or *fast yellow*, is a mixture of sodium amido-azo-benzene-di-sulphonate with sodium amido-azo-benzene-mono-sulphonate. The experiments show that it has a marked and injurious effect on peptic digestion. In each case the amount of fibrin taken was 1 gramme, that of the pepsin 0·020 gramme, and the duration of the digestion was three hours.

	Colour. grm.	Fibrin dissolved. grm.		Colour. grm.	Fibrin dissolved. grm.
1.	0·0	1·0	4.	0·25	0·22
2.	1·0	0·1	5.	0·125	0·35
3.	0·5	0·12	6.	0·062	0·73

The experiments were also carried out with a $\frac{6}{10}$ per cent. solution of hydrochloric acid, with similar results.

Pepsin and Saffoline.—This colour, which was found to be *acridine red*, slightly retarded the digestion of the fibrin, but on the whole the author considered its effect to be practically *nil*.

Pepsin and Magenta.—The fibrin contained in the five test tubes with the same proportions of colour as before dissolved in every case in three and a half hours, so that magenta appears not to interfere with peptic digestion.

For the experiments on pancreatic digestion, the mixture consisted of: water, 100 c.c.; sodium bicarbonate, 1·5 grammes; pancreatin, 0·3 gramme; fibrin, 1·0 gramme. The quantities of pigment added to each tube and the method of digesting were the same as before.

Pancreatin and Oroline Yellow.—This colour, which had so marked an effect in retarding peptic digestion, was found to have no action whatever on the pancreatic ferment, the fibrin in every case dissolving as freely as in the blank experiment.

Pancreatin and Saffoline.—The duration of the experiment was six and a half hours, and the amounts of fibrin and pancreatin 1 gramme and 0·3 gramme respectively.

	Colour. grm.	Fibrin dissolved. grm.		Colour. grm.	Fibrin dissolved. grm.
1.	0·0	1·0	4.	0·25	0·55
2.	1·0	0·0	5.	0·125	0·65
3.	0·5	0·0	6.	0·062	0·75

Tannin precipitated the colouring matter.

Pancreatin and Magenta.—This had as marked an effect as saffoline in retarding digestion.

	Colour. grm.	Fibrin dissolved. grm.		Colour. grm.	Fibrin dissolved. grm.
1.	0·0	1·0	4.	0·25	0·40
2.	1·0	0·0	5.	0·125	0·60
3.	0·5	0·0	6.	0·062	0·73

The solutions in tests 2 and 3 gave no precipitate with tannin, but in all the others the precipitate was either marked or heavy.

Pancreatin and Methyl Orange.—This behaved precisely like the last two, completely stopping the digestion in the two stronger solutions, and retarding it in the three weaker.

From the examination of these four colours, it appears that while none interfere with both peptic and pancreatic digestion, all interfere with one or the other, and are therefore very undesirable in food or drink. C. A. M.

The Detection of Chestnut Leaves in Powdered Senna. L. E. Sayre. (*Amer. Jour. Pharm.*, 1896, lxviii., 587, 588.)—About 0·5 gramme of the No. 60 powder is placed in a layer of uniform thickness on a clean glass slide, below which is a sheet of white paper. One drop of a 5 per cent. solution of ferric chloride is allowed to fall upon the powder, and remains for some time, in the form of a globule, unabsorbed. If any chestnut leaves be present, the particles under the drop will turn a dark blue or black (tannin) in less than thirty seconds. It is stated that a very small percentage of the adulterant can thus be detected.

Under the microscope the adulteration may often be detected by the presence of the tracheids and pitted cells which compose the mid-rib of the chestnut leaf.

C. A. M.

On Maté or Paraguay Tea. B. A. Katz. (*Zeit. Nahr. Untersuch*, 1896, x., 364.)—Pure maté should consist only of the leaves of the *Ilex Paraguayensis*, which have a green colour and a characteristic aromatic smell. It appears, however, that much of that sold in Europe, especially when powdered, is mixed with the stalks of the plant, which contain no caffeine and are valueless. The author's investigations show that the ash from the extract of maté leaves contains a high percentage of manganese and magnesium salts, to which it is thought the plant probably owes some of its physiological properties.

The mean results of the analyses were:

	Per Cent.
Mineral matter	7·24
Moisture...	9·38
Total nitrogen	2·05
Caffeine	1·15
Albuminoids = (N, excluding that of caffeine, × 6·25) ...	10·75
Fat and resin	6·57
Tannin	7·74
Substances soluble in water	31·18
Per cent. ash soluble in water...	36·05
,, ,, ,, HCl	71·24

It is stated that for some time past the young leaves of *Ilex aquifolia* have been used in the Black Forest in the place of Chinese tea. C. A. M.

ORGANIC ANALYSIS.

Examination of Bergamot Oil. A. Borntraeger. (*Zeit. anal. Chem.*, 1896, xxxv., 523-525.)—In a former communication (ANALYST, xxi., 137) the author recommended the determination of the amount of linalol acetate as a test of the purity of an oil, basing his calculations on the standard of 38 per cent. In their recent report,

however, Schimmel and Co. state that for the last crop this amount was seldom reached. In ripe and semi-ripe fruits it was 33-34 per cent., rising to 37 per cent. when the fruits were ripe. Only in a few instances of Parthian bergamot oil towards the close of the season was 40-44 per cent. of linalol acetate found. The difference between these figures and those found by the author and Campolo is largely explained by the fact that the latter were obtained entirely from the examination of sound and ripe fruits of an earlier crop.

The author concludes, therefore, that it is necessary to supplement the saponification process by the density and optical rotation of the oil, and asserts that he never intended the determination of these constants to be superseded. C. A. M.

A Reaction for Morphine. C. Kippenberger. (*Zeit. anal. Chem.*, 1896, xxxv., 421.)—On adding to the solution of a morphine salt an alkaline hydroxide, and then a solution of iodine in potassium iodide, containing as little as possible of the latter salt, a yellow colour is obtained, which, on the gradual addition of more iodine, changes to a grass green. This is probably due to a process of oxidation. An analogous reaction is obtained with bromine, but is more uncertain than in the case of iodine. Chlorine by itself does not give the colour, but on adding potassium iodide to the solution after the addition of chlorine, it is immediately produced. Apomorphine, treated in the same manner, gives a brown coloration and then a precipitate. Other alkaloids, including codeine, do not show any abnormal behaviour with the reagent. C. A. M.

A New Method for the Quantitative Estimation of Alkaloids. C. Kippenberger. (*Zeit. anal. Chem.*, 1896, xxxv., 407-421.)—This is based on the fact that the compounds formed on treating alkaloids with iodised potassium iodide are soluble in acetone, and that on adding an aqueous solution of an alkaline hydroxide, alkali-metal iodide and iodate are formed, while the alkaloid remains in solution as hydriodide. The addition of an acid liberates the iodine from the iodate, and on titrating this free iodine with thiosulphate, an acidified aqueous solution of the alkaloid salt is obtained, from which, after evaporation of the acetone on the water bath and addition of an alkali, the alkaloid can be extracted with ether or chloroform (preferably the latter). Experiments with weighed quantities of the most commonly occurring alkaloids gave absolutely quantitative results when estimated by this process.

In the isolation of alkaloids from cadaveric remains, etc., the reactions for the alkaloids are often masked by the presence of other bodies, such as amines, amido acids, proteids, etc. In such cases the author extracts the supposed alkaloid by one of the usual processes, neutralizes the acidified solution, and adds a solution of iodine in potassium iodide, containing 12·7 grammes of iodine and 60 grammes of potassium iodide per litre, and as much more of the latter as is required to completely dissolve the iodine. After several hours, the precipitate is collected on an asbestos filter, washed several times with cold water, and dissolved in acetone. The solution is first made alkaline, then acidified, and then mixed with water, and the nearly colorless

liquid then contains the alkaloid as an acid salt. The acetone is evaporated in the water-bath, a little sodium thiosulphate solution added to the still warm liquid, then a slight excess of sodium carbonate, and the alkaloid extracted with chloroform or ether. With morphine or narceine a different method of extraction must be used, viz., amyl alcohol or chloroform from an ammoniacal solution, or chloroform with alcohol from an alkaline carbonate solution. Since glucosides do not react with iodine in potassium iodide, the method offers a means of separating them from alkaloids. The author's experiments on mixtures of alkaloids with the various substances likely to occur in decomposing organic matter show the reliability of the method.

The method is similarly applicable to the estimation of alkaloids in plant extracts. The extract is dissolved in acidified water, neutralized, and the alkaloid precipitated with iodine in potassium iodide. The precipitate is collected, preferably on asbestos in a Gooch's crucible, well washed with cold water, and dissolved in as little acetone as possible. The solution is treated with acid and alkali as before, then mixed with water, and shaken twice with petroleum spirit (B.P., 30° to 50° C.), which removes most of the acetone as well as impurities possibly present. The alkaloid is then extracted from the aqueous solution after the addition of sodium thiosulphate and sodium carbonate, as described above.

In order to prevent the alkaloid becoming brown during the evaporation of the solvent on the water-bath, the author recommends the presence of a trace of alkali. This is introduced by adding ether, which has been shaken with sodium carbonate, to the extraction solvent, and the error thus caused may be neglected, since that introduced by the variation in the amounts of water of crystallization of alkaloids is often greater. Ammonia is not suitable for the purpose, since it is volatile during the drying.

Objection is taken to the common method of isolating pure alkaloids by adding acid to the ethereal solution of the alkaloid bases, on the ground that when ammonia has been used to set free the alkaloid, the ammoniacal salt has been simultaneously precipitated. Moreover, in the case of old cadaveric matter, the salts of amido bases will also be separated. C. A. M.

Estimation of Alkaloids by Titration with Iodine Solution III. C. Kippenberger. (*Zeit. Anal. Chem.*, 1896, xxxv., 422-471.)—The author has continued his investigation on this subject (*cf.* ANALYST, xx. 201, and xxi. 191), and has arrived at the following conclusions:

1. For the accurate volumetric estimation of alkaloids in general in aqueous solution by means of iodine solution, it is necessary to standardize the latter against a weighed quantity of the given alkaloid. The most suitable strength for the iodine solution is $\frac{1}{10}$ or $\frac{1}{20}$ N. (This is a recapitulation of the conclusion drawn in the author's second paper—ANALYST, xxi. 192.)

2. The salts of strychnine and brucine, however, in aqueous solution react according to the equation $Alk.HCl + KI + I_2 = Alk.HI.I_2 + KCl$, when there is an excess of iodine, and 1 molecule of the alkaloid corresponds to 2 molecules of iodine. The best strength is $\frac{1}{20}$ N. iodine solution in 6 to 8 per cent. potassium iodide.

3. Morphine also may be titrated as in (2), provided the amount of potassium

iodide be increased. It is preferable to replace potassium iodide by potassium bromide, which is added in the solid form to the neutral morphine solution until a white precipitate appears. The iodine solution is then added, and, after standing for some time, the excess of iodine titrated with standard thiosulphate. Morphine may also be estimated in as neutral as possible solution of the sulphate by adding an excess of barium iodide and then the iodine solution. Accurate results may be obtained with quinine in aqueous solution by adding a large amount of potassium bromide, and using the iodine solution in only slight excess.

4. All the alkaloids may be accurately titrated by dissolving them in a known quantity of hydrochloric or sulphuric acid (the solution being as concentrated as possible), adding a calculated amount of silver iodide, then the iodine solution, filtering after two to three minutes, and titrating the excess of iodine in an aliquot portion of the filtrate. The silver iodide solution is prepared by dissolving 1·0 gramme $AgNO_3$ and 10 grammes of KI in 20 c.c. of water. The iodine solution $\frac{1}{20}$ N. To calculate the amount of silver iodide solution required, the factors 4·7 and 3·5 are employed for hydrochloric and sulphuric acids respectively, and the result when using this strength of silver iodide multiplied by 20. For example: 0·1 gramme of narcotine dissolved in 10 c.c. of water, containing 0·5585 per cent. hydrochloric acid, 0·05585 gramme $HCl \times 4{\cdot}7 = 0{\cdot}262495$ gramme AgI and this $\times 20 = 5{\cdot}2$ c.c., the amount of silver iodide solution required to convert the alkaloid hydriodide into the periodide. An excess of silver iodide must be avoided, but should it have occurred, the double salt of the alkaloid and silver which may precipitate may be dissolved by adding more potassium iodide. The details of the manipulation are the same as those given by the author in his first paper (see ANALYST, xx., 203, *Iodine Solution*). In the case of quinine, it must not be lost sight of that the compound $C_{20}H_{24}N_2O_2(HI)_2.I_4$ is formed, and that therefore 4 equivalents of iodine correspond to 1 molecule of the alkaloid. C. A. M.

The Estimation of Acetone in Urine. **G. Argenson.** (*Bull. Soc. Chim.*, 1896, 1055-1058.)—In this method, which is based on Léoben's reaction, the acetone is separated by distillation from the urine, transformed into iodoform by means of iodine and potash, the iodoform treated with alcoholic potash, and the potassium iodide formed titrated with decinormal silver nitrate solution.

On distilling urine containing acetone, the whole of the latter passes over in the first quarter of the distillate. To obviate the frothing somewhat, a little vaseline may be added, but constant attention is required.

In making a determination, 200 c.c. of the urine are distilled, and the first 50 c.c. of the distillate collected. To this are added 10 c.c. of an aqueous solution of potash (23° Bé., S.G. 1·186), and 5 c.c. of an iodine solution prepared by dissolving 105 grammes of iodine in a litre of water containing 180 grammes of potassium iodide.

The precipitate is collected on a filter, washed until the washings give no opalescence with silver nitrate, and introduced into a flask containing 20 c.c. of a concentrated alcoholic solution of potash free from haloid salts. The filter-paper is freed from the small amount of iodoform clinging to it by shaking with a mixture of ether

and alcohol in a stoppered flask, the solution being subsequently added to the main bulk.

After being boiled for several minutes to complete the reaction, the liquid is cooled, neutralized with acetic acid, and diluted to 200 c.c. An aliquot portion is then titrated with decinormal silver nitrate, potassium chromate being used as indicator, and from the number of c.c. used the weight of acetone is calculated.

The reactions involved are:

(1) $CH_3.CO.CH_3 + 3I_2 + 4KOH = CHI_3 + CH_3COOK + 3KI + 3H_2O$

and

(2) $CHI_3 + 4KOH = 3KI + HCOOK + 2H_2O$.

According to the first equation, one molecule of acetone should give one molecule of iodoform; but in practice the quantity obtained is always less than that required by theory, and is not proportional to the amount of acetone in the solution. It is, therefore, essential to always work under identical conditions; and for use with his exact mode of proceeding the author has constructed the following table of reference, in which is given the weight of acetone corresponding to the volume of silver nitrate solution used.

$\frac{N}{10}$ Silver Nitrate, c.c.	Grammes of Acetone per litre of Urine.	$\frac{N}{10}$ Silver Nitrate, c.c.	Grammes of Acetone per litre of Urine.

C. A. M.

New Colour Reaction of Colza Oil. Palas. (*La Nature*, August 22, 1896; through *Ann. de Chimie Analyt.*, vol. i. [22], p. 434.) — The rose-red coloration produced by agitating colza oil with rosaniline bisulphite is peculiar to this oil; olive oil forms a more or less white emulsion, whilst sesame, cotton-seed, arachis, ricinus, and almond oils are decolorized, turnip, nut, and poppy oil remain unchanged, and linseed oil forms a bright yellow emulsion. The fatty acids of colza oil give no coloration.

The reaction is sufficiently delicate to detect 2 per cent. of colza oil in olive oil.

To prepare the reagent, which should be colorless, 30 c.c. of a 1 per cent. solution of fuchsin, 20 c.c. of 34° B. (S.G. 1·308) sodium bisulphite, 200 c.c. of water, and 5 c.c. of sulphuric acid, are mixed together in the cold. C. S.

On the Rancidity of Fats. E. Spaeth. (*Zeit. anal. Chem.*, 1896, xxxv., 471-493.)—After a long experimental investigation on this subject, the full details of which are given in the original paper, the author has arrived at the following conclusions:

1. The rancidity of fats (lard) is an oxidation process, caused essentially by the action of light and atmospheric oxygen. The unsaturated acids (oleic) are first attacked with the formation of acids containing less carbon, and subsequently aldehydic substances and oxy-acids are produced.

2. During the course of oxidation and formation of free acids, the amount of volatile acids is considerably increased (*cf.* ANALYST, xxi., 298).

3. All the acids present have a share in the formation of the free fatty acids.

4. As the oxidation proceeds, the absorptive capacity (for iodine) of a fat correspondingly decreases, owing to the above-mentioned oxidation and decomposition of the unsaturated fatty acids and their polymerization. Fats thus oxidized have a considerably higher refractive index than have the normal fats, which must be attributed to the polymerization of the unsaturated fatty acids.

5. In general, fats which have become rancid have a higher melting-point than that shown by the fresh fats. C. A. M.

On the Iodine Number of Cocoa Butter. F. Filsinger. (*Zeit. anal. Chem.*, 1896, xxxv., 517-521.)—Referring to the figures published by Strohl (ANALYST, xxi., 231), the author suggests that the higher limit (41·7 per cent.) might have been due to the presence of a certain amount of free fatty acids in the samples, which would obviously absorb more iodine than the neutral fat. From the results of the examination of cocoa butter from all sources made in conjunction with R. Henking in 1889, he came to the conclusion that the iodine number varied from 33·5 to 37·5 per cent. C. A. M.

INORGANIC ANALYSIS.

Determination of Oxygen by Alkaline Pyrogallol. F. Clowes. (*Chemical News*, vol. lxxiv., p. 199.)—An evolution of carbon monoxide occasionally takes place when oxygen is absorbed by alkaline pyrogallol solution, which, unless determined by absorption with cuprous chloride, falsifies the estimation. This can be prevented by using a sufficient excess of potassium hydroxide. The following proportions are recommended: 160 grammes of potassium hydroxide and 10 grammes of pyrogallol in 200 c.c. of solution, made by dissolving the hydroxide in 130 c.c. of water, and adding the pyrogallol to this. C. S.

On the Standardization of Potassium Permanganate. E. Riegler. (*Zeit. anal. Chem.*, 1896, xxxv., 522.)—The alteration in the strength of a solution of oxalic acid is prevented by the addition of a sufficient quantity of sulphuric acid. A solution prepared by dissolving 9·9654 grammes of pure oxalic acid in about 500 c.c. of water, adding 50 c.c. of concentrated sulphuric acid and making up to a litre, did not change in the slightest degree after standing for a year. Twenty c.c. of such a solution correspond to 100 milligrammes of potassium permanganate. C. A. M.

On the Estimation of Sulphur in Inorganic Sulphides. P. Jannasch and O. Heidenreich. (*Zeit. f. anorg. Chem.*, xii., 5, 358.)—The paper describes the analysis of commercial stannic sulphide by the method previously suggested (ANALYST, xvii., 197). The sulphide is heated in a weighed tube, through which oxygen is passed, until the sulphur is driven over into the receiver, the tube with its contained stannic oxide being afterwards weighed when cool. The receiver may contain either 3 to 4 per cent. hydrogen peroxide, or a mixture of very dilute hydrochloric acid with excess of bromine. C. H. C.

Gravimetric Estimation of Selenium. A. W. Pierce. (*Zeit. Anorg. Chem.*, xii., 6, 409.)—To avoid the tedious and frequently incomplete precipitation of selenium by sulphurous acid, the author substitutes potassium iodide in an acid solution as the reducing agent. The following procedure is given as the best: The solution containing the selenium is diluted to 400 c.c., acidified with hydrochloric acid, and three grammes of potassium iodide added; the solution is then boiled for ten to twenty minutes, when the selenium will be precipitated as the black modification, and will be found to be entirely free from mechanically held iodine. The selenium thus thrown down is collected on an asbestos filter, washed and dried at 100° C. until constant in weight. The precipitation and filtration can be carried out in thirty minutes. Both selenious and selenic acids can be estimated as shown above, but in the case of selenic acid the iodine is not liberated until the solution is boiled; and in order to complete the reaction the solution must be boiled for some time. Although selenic acid cannot be determined in the presence of selenious acid, the method has the advantage that the total selenium in a solution can be rapidly determined, whether it is present as selenic or selenious acid. H. C. L. B.

Brucine as a Reagent for the Detection of Nitrous Nitrogen in Presence of Sulphites. P. Pichard. (*Comptes rendus*, vol. cxxiii., p. 590.)—Brucine gives, with hydrochloric acid, a vermilion to yellow coloration in presence of nitrites, and by this test $\frac{1}{2\,4\,0\,0\,0\,0}$ part of nitrous nitrogen can be detected in solution. It is suitable for use in the examination of such bodies—drainage-waters, etc.—as contain nitrites and sulphites, the latter of which interfere with the accuracy of the Picini, Tromsdorff, and Griess nitrogen reactions. The substance is tested for sulphides by lead acetate, and for sulphites by a strong acid, and, if sulphur dioxide is detected, the brucine test is applied in the following manner. A drop of hydrochloric acid is first

added, and then small portions of brucine. In five minutes or so a tint varying from vermilion red to bright yellow appears if nitrites are present.

Brucine gives no coloration with chlorine or hypochlorites, but the following salts of brucine—nitrate, chloride, acetate, and (especially) sulphate—will give a vermilion red with these bodies. C. S.

Arsenical Sulphuric Acid a Source of Error in the Naumann-Wagner Process for the Estimation of "Available" Phosphoric Acid. G. Loges and K. Mühle. (*Chem. Zeit.*, 1896, xx., 984.)—Naumann's process for estimating the phosphoric acid in the Wagner extract of a slag—which consists in a destruction of the citric acid by means of 25 c.c. of sulphuric acid and 30 c.c. of strong nitric acid, followed by a direct precipitation with magnesia mixture—is so much quicker and less troublesome than the ordinary method that it is becoming very generally used. Occasionally some irregularities occur in the results obtained, and these appear to be due to the presence of arsenic in the sulphuric acid employed. In one instance, where the authors used an acid freed from nitrogen (for Kjeldahl estimations) by arsenious acid, they found 18·01 per cent. of available acid in a sample that only contained 17·68 per cent. of total phosphoric acid, the magnesium pyrophosphate being, of course, contaminated with the corresponding arsenate. F. H. L.

Detection of Fluorine in Silicates and Borates. J. A. Reich. (*Chem. Zeit.*, 1896, xx., 985.)—The material is moistened with sulphuric acid and placed in a crucible, which is covered with a watch-glass, convex side down, having a drop of water on its under surface. If any fluoride of silicon or boron is given off, a white layer of silica or boric acid will be found at the edge of the drop, and, after evaporation, will appear as an etched line. The two substances may be distinguished by treatment of the deposit with water, and by the turmeric-paper test for boric acid. F. H. L.

Estimation of Boric Acid. Schneider. (*Chem. Zeit.*, 1896, xx., 822.)—This process depends on the fact that boric acid is completely volatilized on distillation from an alcoholic solution. The material to be analysed is extracted under a reflux condenser with boiling absolute alcohol, the liquid cooled and filtered, and the residue washed with the same solvent. Raw flesh, however, is preferably cut up into fragments, and cooked in a well-covered beaker immersed in a water-bath. The mass is then cooled, rubbed down to a powder, an equal weight of anhydrous sodium sulphate added to absorb the water, and the whole extracted with alcohol as before. The solution is distilled from a flask immersed up to its neck in the water-bath till all the alcohol has passed over; and if turmeric paper shows that the last drops of the distillate still contain boric acid, more alcohol is introduced into the flask and the distillation repeated. A quantity of freshly-melted sodium carbonate is dissolved in water, and the alcoholic solution added gradually. The mixture is evaporated to dryness, the residue weighed, fused, and weighed again, the boric acid being calculated from the loss.

F. H. L.

The Solubility of Barium Sulphate. F. W. Küster. (*Zeit. f. anorg. Chem.*, xii., 4, 261-271.)—The author criticises the methods employed, and combats the conclusions arrived at, by Fresenius and Hintz, as set forth in their paper on "The Abnormal Solubility Ratio of Barium Sulphate" (*Zeit. f. anal. Chem.*, xxxv., 170-183). The results they obtained are not only at variance with the author's own experiments, but also with the observations of Kohlrausch and Rose (*Zeit. f. phys. Chem.*, xii., 241), and of Hollemann (*ibid.*, xii., 130), who employed more exact methods. The author concludes that the figures given by Fresenius and Hintz for the solubility of barium sulphate in pure water are incorrect, their solutions being obviously supersaturated, and gives 1 in 425,000 for the solubility in pure water at 18·3° C. (Fresenius 1 in 100,000, Kohlrausch and Rose 1 in 436,700, and Hollemann 1 in 429,700). He also shows that the solubility figures for barium sulphate in solutions of salts and in acids are in no way abnormal, but are quite in accordance with the modern theory of solution. C. H. C.

The Examination of Commercial Thorium Nitrate and Separation of Thorium from Cerium. R. Fresenius and E. Hintz. (*Zeit. anal. Chem.*, 1896, xxxv., 525-544.)—The authors examined 11 incandescent mantles, manufactured between March and October, 1895, which consisted principally of thoria (96·42 to 99·06 per cent.) and ceria (0·38 to 2·02 per cent.) with the object of determining whether the ceria was an accidental impurity in the thorium nitrate used, or had been intentionally added.

The sources of thorium nitrate are monazite, containing about 4 to 5 per cent. of thoria and 50 to 60 per cent. of oxides of the cerium group (ceria, neodidymia, lanthana); and Norwegian thorite or orangite, in which the thoria varies very greatly (often being 50 per cent.), but in which the percentage of the other earths, yttria, ceria, etc., is invariably small. In the preparation of thorium nitrate the purification of thorite is therefore considerably easier than that of monazite.

Three specimens of thorium nitrate, in use during March to October, 1895, one of which had been prepared from monazite, were analysed in the following manner: Twenty grammes of the thorium nitrate were dissolved in about 3 litres of water, sodium thiosulphate added, and the liquid boiled. The precipitate was filtered off, washed, and dissolved in hydrochloric acid. Any sulphur remaining undissolved was burned off, the ash fused with acid potassium sulphate, dissolved in dilute hydrochloric acid, and precipitated with ammonia. The precipitate was washed, dissolved in hydrochloric acid, and the solution added to the main solution. The whole was evaporated to dryness, the residue taken up with water and a few drops of hydrochloric acid, and again precipitated with sodium thiosulphate. The precipitate was filtered off and washed.

The filtrates from the first and second thiosulphate precipitations were treated with ammonia, the precipitates dissolved in hydrochloric acid, the solutions united, evaporated to dryness, and the residue taken up in slightly acidified water and again boiled with sodium thiosulphate. This treatment was again repeated. The filtrates from the two last thiosulphate precipitates were precipitated with

ammonia, the precipitates washed, dissolved in nitric acid, and the united solutions again precipitated with thiosulphate. The filtrate was treated with ammonia, and the resulting precipitate filtered off, washed, and dissolved in nitric acid. The solution was evaporated to dryness, the residue taken up with water, and precipitated, warm, with oxalic acid.

The precipitate (containing cerium, yttrium, lanthanum, and neodidymium) was ignited and weighed, fused with acid potassium sulphate, dissolved, ammonia added, and the precipitate filtered off, washed, and dissolved in hydrochloric acid. The solution was nearly neutralized with sodium carbonate, and boiled after the addition of sodium acetate, acetic acid, and sodium hypochlorite. The precipitate was filtered off, washed, dissolved in hydrochloric acid, and again precipitated in the same way. It was then washed, dissolved in nitric acid, precipitated with ammonia, filtered off, washed, ignited, and weighed as cerium oxide.

The filtrate was acidified with hydrochloric acid, boiled, and decomposed with ammonia. The precipitate was filtered off, washed, and dissolved in hydrochloric acid. The solution was evaporated to dryness, the residue taken up in a few drops of water, and precipitated by means of a saturated solution of potassium sulphate. After standing some time the precipitate was filtered off, and washed with the saturated solution of potassium sulphate, dissolved in water containing a few drops of hydrochloric acid, precipitated with ammonia, filtered off, washed, and dissolved in nitric acid. The solution was evaporated to dryness, the residue taken up in water, precipitated with oxalic acid, and the precipitate collected, washed, ignited, and weighed. It contained the neodidymium and lanthanum oxides.

The filtrate from the potassium sulphate precipitate was precipitated with ammonia, washed, dissolved in nitric acid, and again precipitated with ammonia, washed, ignited, and weighed as yttrium oxide. Thorium oxide was estimated by difference.

The results thus obtained were:

	Thorium Nitrate (from Monazite). E. Merck. August, 1895. Per cent.	Thorium Nitrate. E. de Haën. July, 1895. Per cent.	Thorium Nitrate. E. de Haën. March, 1895. Per cent.
Thoria	47·2600	46·2066	44·9410
Ceria	0·0885	0·0463	0·0910
Neodidymia (including lanthana)	0·0940	0·0521	0·0665
Yttrium oxide ...	0·1430	0·0373	0·0070
Nitric acid, water, and acids not estimated	52·4145	53·5823	54·8945
Zironia	—	trace	—
Lime, magnesia, iron silica	—	0·0754	—
	100·0000	100·0000	100·0000

Calculated on the substance left after burning in an incandescent mantle, these corresponded to:

	Per cent.		Per cent.		Per cent.
Thoria	99·817	...	99·546	...	99·635
Ceria	0·186	...	0·100	...	0·202
Neodidymia (including lanthana)	0·197	...	0·112	...	0·147
Yttria	0·300	...	0·080	...	0·016
Zirconia	—	...	trace	...	—
Lime, magnesia, iron silica	—	...	·162	...	—
	100·00		100·000		100·000

Since the amount of ceria found in the 11 mantles (average 1 per cent.) was about five times as great as that contained in the most impure of the samples of thorium nitrate when calculated on the total quantity of oxides that would be left in a mantle after burning, the authors concluded that either the ceria was intentionally added, or that the thorium nitrate used was of a much less degree of purity than was attainable in 1895.

To confirm this view, they made mixtures containing 2·02 and 0·38 per cent. of ceria, the highest and lowest limits found in the eleven mantles, and showed that by precipitating the solutions three times with sodium thiosulphate, and then precipitating the filtrates with oxalic acid as described above, from 97 to 98 per cent. of the cerium oxide taken could be recovered, so that the methods known to chemists in 1895 were quite sufficient to effect a far greater amount of separation of cerium from thorium than was the case in the mantles analysed. C. A. M.

The Separation of Thorium from the other rare Earths by means of Potassium Trinitride. L. M. Dennis. (*Jour. Amer. Chem. Soc.*, 1896, xviii., 947-952.)—It is shown that thorium can be quantitatively separated from the other rare earths by adding a solution of potassium trinitride to a neutral solution of the rare earth salts. This reaction may be attributed to the weak basicity of thorium, and the author's experiments show that it may be represented by the equation

$$Th(NO_3)_4 + 4KN_3 + 4H_2O = Th(OH)_4 + 4KNO_3 + 4HN_3.$$

The reagent is prepared by neutralizing a dilute solution of hydrazoic acid with a dilute solution of pure caustic potash, and then adding sufficient hydrazoic acid to give a distinctly acid reaction.

In the test experiments with thorium alone, a solution of pure thorium chloride was employed which contained in 1 c.c. an amount corresponding to 0·00521 gramme of ThO_2, as determined by precipitation with ammonia. On adding to this solution a few c.c. of potassium trinitride solution, and boiling for one minute, a flocculent precipitate was obtained. This was washed by decantation with hot water, transferred to a filter, ignited, and weighed as ThO_2. The amount of thorium dioxide obtained was 0·00520 gramme in 1 c.c. Some of the results with mixtures of pure salts of thorium, cerium, lanthanum, and didymium are given in the following table.

		Taken.	Found.

C. A. M.

A Sensitive Form of the Diiodide Reaction for the Detection of Mercury. **P. Jannasch.** (*Zeit. f. anorg. Chem.*, xii., 2, 143-145.)—For the ready recognition of minute traces of mercury the author operates as follows: Deposit the mercury on copper foil by warming in a slightly acid solution, pour off the solution, wash the metal with cold water, and dry with a minimum of friction by means of blotting-paper. Put the amalgamated copper at the bottom of a long narrow test-tube, remove the last traces of water by sucking air out of the tube. Draw out the latter in the middle to capillary bore. By careful heating drive the mercury into the shoulder under the constriction, divide the tube at the drawn-out part, cut off the closed end, and place the portion containing the sublimate in a cylinder containing a small fragment of iodine. The mercury, when converted into iodide, appears scarlet in thick and yellow in very thin layers. Half a milligram of mercuric chloride yielded a sublimate of mercury which was practically invisible, but was easily distinguished when converted into iodide.

A still more delicate method is to place the mercury-covered slip of copper foil on a watch-glass close to, but not touching, a small fragment of iodine. Cover with another watch-glass, and allow to stand for ten minutes. A deposit of mercuric iodide of the same shape as the foil is formed on the glass, and may be further identified by the microscope. In this way 0·01 milligram of mercuric chloride may be detected.

C. H. C.

The Separation of Mercury from Tin. **P. Jannasch and H. Lehnert.** (*Zeit. f anorg. Chem.*, xii., 2, 132, 133.)—The same apparatus is used as for the estimation of sulphur in sulphides (ANALYST, xvii., p. 197).

Fill the receiver with dilute nitric acid, dissolve the mixed salts in strong nitric acid, evaporate off the excess of acid, dilute to about 300 c.c., add 5 c.c. concentrated sulphuric acid, heat gently, and precipitate with hydrogen sulphide. Wash the precipitate with warm water, dry at 90° C. Detach the precipitate from the filter as thoroughly as possible, cut up the latter into small pieces, and burn in the combustion tube with suitable precautions for avoiding the distillation of tarry products, cool the apparatus, add the main bulk of the precipitate and burn this also. Mercury distils over, while stannic oxide remains behind, and can be weighed. Dissolve the mercury in the receiver by evaporating the combined liquids and adding sulphuric acid. Remove nitric acid as far as possible by evaporation, dilute largely with water, and precipitate the mercury as sulphide; filter, wash, dry and weigh. C. H. C.

The Separation of Mercury from Antimony, Copper, and Arsenic. P. Jannasch. (*Zeit. f. anorg. Chem.*, xii., 5, 359-364.)

(1) *Mercury from Antimony.*—The metals are precipitated as sulphides, filtered off, washed, and dried at 95° C. The precipitate is removed from the filter and placed on one side, the filter-paper cut into strips, rolled up, and placed in the tube of the apparatus previously described (ANALYST, xvii., 197), the receiver of which is filled with dilute nitric acid. Fuming nitric acid is then gradually added until the tube is about a quarter full, when it is immersed in hot water (or heated very carefully over a naked flame) until solution is complete. The excess of acid is evaporated off by heating to 90° or 100° C. (in a phosphoric acid bath) in a current of dry air or carbonic acid. The black residue is treated with the same volume of acid and dried once more, then the precipitate introduced, washing in the last particles with dilute nitric acid. Concentrated (ordinary) nitric acid is added, dried as before, and evaporated twice with the fuming acid, finally raising the temperature to 150° to 180° C. The tube is then connected with the oxygen supply and the receiver, and heat applied, beginning at the receiver end, till all the mercury is expelled from the tube. When the apparatus is quite cold, the residual SbO_2 may be weighed direct, or may be converted into sulphide by fusion with sulphur iodide in a stream of sulphuretted hydrogen, subsequently driving off the excess of sulphur, and heating the residual Sb_2S_3 in a stream of bromine (see *Berichte*, xxvi., 1422, *Zeit f. an. Chem.*, ix., 201). The mercury is estimated in the receiver in the manner already described.

(2) *Mercury from Copper.*—The metals are precipitated as sulphides, washed, and dried, the precipitate separated from the filter, and the latter burnt in the weighed combustion-tube in a stream of oxygen The precipitate is then introduced and heat applied, at first gently, and then more strongly, a stream of oxygen being maintained in the tube until all the mercury is driven over into the receiver (which contains a mixture of dilute nitric acid and bromine water). Weigh the residual cupric oxide directly by heating the tube till constant in weight, or dissolve in hydrochloric or nitric acid and precipitate with soda, etc. Estimate the mercury as before.

(3) *Mercury from Arsenic* —The nitric acid solution of the mixture is introduced into the combustion-tube of the apparatus and dried by heating in a phosphoric acid bath in a current of dry air. The residue is then taken up with a drop of water, 0·6 gramme of magnesia free from chlorine added, well mixed, and again evaporated to dryness, the temperature being finally raised to 180° C. After removing the tube from the phosphoric acid, it is cleaned externally, connected with the oxygen supply, and heated until all the mercury is expelled into the receiver (containing dilute nitric acid and 15 c.c. hydrogen peroxide). The tube is allowed to cool gradually, the residue dissolved in 5 c.c. concentrated nitric acid, transferred to a beaker, 0·3 gramme of citric acid added and excess of ammonia, and the arsenic estimated as magnesium arseniate or ammonium magnesium arseniate. C. H. C.

Notes on Reinsch's Test for Arsenic and Antimony. J. L. Howe and P. S. Mertins. (*Jour. Amer. Chem. Soc.*, 1896, xviii., 953-955.)—The fact that arsenious oxide and antimonious oxide (Sb_2O_3) crystallize in isomorphous forms, has led to the

conjecture that the antimonious oxide subliming from the copper might sometimes be mistaken for arsenic. To settle this point, the authors have made a large number of determinations with different salts of the two substances, and with the various organs of two cats poisoned by tartar emetic. The degree of heat required to sublime the antimony was perceptibly higher than in the case of arsenic, and out of 185 tests not one yielded a sublimate of antimonious oxide showing under the microscope any trace of crystallization. They conclude, therefore, that this corroborative negative evidence must be considered to have the weight of positive evidence.

With reference to the substances tested the following notes are recorded: (1) All arsenious compounds soluble in hydrochloric acid give the deposit on copper immediately on heating. (2) Commercial "metallic" arsenic readily gives a deposit. (3) Freshly-sublimed "metallic" arsenic (bright crystals) gives no deposit. (4) Arsenates deposit only after several minutes' boiling. (5) In the presence of nitric acid or chlorates no deposit is obtained, owing to the copper dissolving. (6) When aqua regia or potassium chlorate have been used to dissolve the arsenic compound, the solution should be evaporated to dryness with hydrochloric acid, and tested, as in the case of arsenates. (7) Presence of organic matter does not affect the test. (8) If much arsenic be present, only a small portion of the substance should be taken, as when a large amount of arsenic is deposited on the copper it does not adhere with firmness. (9) Antimony is not deposited as rapidly as arsenic, and the deposit has a violet tint, very distinct from the iron-gray deposit of arsenic. C. A. M.

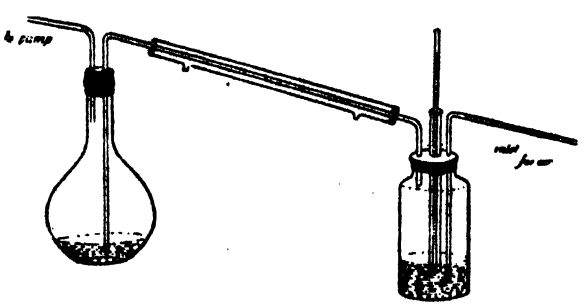
On the Separation of Bismuth from the Metals of the Copper and Iron Groups. P. Jannasch and S. Grosse. (*Zeit. f. anorg. Chem.*, xii., 5, 398.)—The authors, in the course of a large number of separations of arsenic from the metals of the copper and iron group by their dry distillation process (*Zeit. f. an. Chem.*, ix., 274), have observed that bismuth, like tin, may be readily volatilized in a stream of hydrochloric acid, and found on this reaction a process for the separation of tin from the other metals of the above-mentioned groups. C. H. C.

Analysis of "Cap Composition." F. W. Jones and F. A. Wilcox. (*Chemical News*, vol. lxxiv., p. 283.)—Having found that mercury fulminate is soluble in acetone saturated with ammonia, the authors have utilized this property for separating the fulminate from antimony sulphide and potassium chlorate in the analysis of "cap composition."

The carefully-ground substance is placed on a tared filter-paper (previously moistened with the solvent and inserted in a tapped funnel) and exposed to the action of acetone saturated with ammonia for three or four hours. It is then washed with the same solvent until the washings no longer give coloration with ammonium sulphide, and afterwards washed with acetone until the washings leave no residue or evaporation. The residue is dried and weighed; the loss in weight represents the mercury fulminate. The potassium chlorate is then extracted by washing with water, the antimony sulphide being left behind.

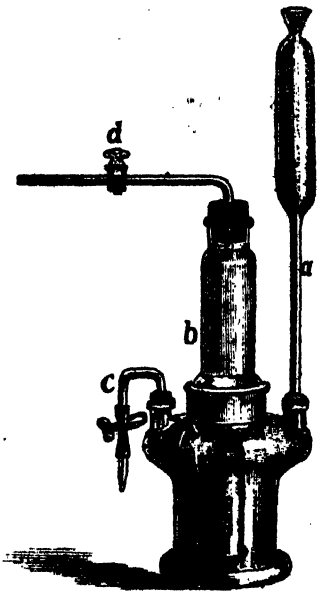
Two analyses of mixtures of known composition are given, viz.:

	A.		B.	
	Percentage taken.	Percentage found.	Percentage taken.	Percentage found.
Antimony sulphide ...	36·47	36·25	37·34	37·22
Potassium chlorate ...	33·25	33·71	46·03	46·43
Mercury fulminate ...	30·27	30·02	16·61	16·34



C. S.

A New Method of Converting Sulphates into Chlorides. P. Jannasch. (*Zeit. f. anorg. Chem.*, xii., 3, 223-224.)—The author points out that the method (ANALYST, xxi., 51), of decomposing silicates by means of boric acid is suitable for the conversion of sulphates into chlorides, as during the fusion all the sulphuric acid is expelled, and its place is taken by the hydrochloric acid subsequently employed for the solution of the melt. C. H. C.



Iodimetric Method for the Determination of Carbon Dioxide. J. K. Phelps. (*Zeit. f. anorg. Chem.*, xii., 6, 431.)—This method consists of the absorption of carbon dioxide by a cold saturated solution of barium hydroxide; the excess of barium hydroxide is then neutralized by iodine, and the excess of iodine added is titrated with a standard solution of arsenious acid. H. C. L. B.

APPARATUS.

A Simple Method for Obtaining a Low Temperature. C. E. Sage. (*Pharm. Journ.*, 1896, p. 397.)—The apparatus consists of a 6-oz. wide-mouthed bottle fitted with a cork pierced with three holes, one of which is large enough for a test-tube, and the others for an inlet and outlet air-tube. The inlet tube passes nearly to the bottom of the flask, while the other passes only a short distance through the cork, and is connected at the other end with a condenser. The flask is partially filled with ether, and the sample to be examined (oil, etc.) is placed in the test-tube, together with a thermometer. Air is now forced or drawn through the ether, which, as it evaporates rapidly, cools the tube, and a temperature of from - 4° to - 5° C. can be easily maintained for a long period. Most of the evaporated ether is retained by the condenser, and the air leaving the condenser can be washed by bubbling through a flask of water before being allowed to escape. C. A. M.

An Improved Laboratory Gas Apparatus. R. Barge. (*Chem. Zeit.*, 1896, xx., 955.)—As shown in the accompanying illustration, this apparatus possesses several advantages over the ordinary Kipp's generator. The portion *b* is closed at its narrowest part by a perforated rubber stopper, on which the substance to be decomposed rests. Just below this point, and near the level of the acid in the lower vessel, a small hole is made in the side, so that while the spent liquid passes down to the bottom, the fresh acid is forced by the pressure given by the tube *a* through this aperture, and therefore reaches the solid without contamination. It is claimed that 94 per cent. of the acid required to work the apparatus is thus made available. The base of the tube *a* is cut off slightly below the level of the stopper; consequently a small quantity of liquid only rises into *a* when the cock *d* is shut, and the stability of the apparatus is not impaired.

The author also remarks that the ordinary Kipp can be improved in this latter respect by cutting off the long central tube just below the top of the bottom bulb, and by replacing the usual stopper by a tube and clip similar to the one shown at *c*. F. H. L.

MISCELLANEOUS.

Alcoholic Fermentation. Eduard Buchner. (*Ber. d. d. Chem. Gesell.*, 1897, p. 117.)—The author has succeeded in obtaining an extract from yeast which apparently possesses the power of causing alcoholic fermentation. One kilogramme of pressed brewers' yeast was triturated with an equal weight of quartz-sand and 250 grammes of kieselguhr until a plastic mass was obtained. With this 100 c.c. of water were intimately mixed, and the whole submitted to a pressure of 400 to 500 atmospheres in a hydraulic press. The resulting cake was then powdered, another 100 c.c. of water mixed with it, and the treatment repeated. In this way 500 c.c. of an extract were obtained, which, after being passed through a Berkefeldt filter, was able to induce fermentation in solutions of maltose, glucose, lævulose, or cane-sugar. The yeast extract was a slightly opalescent fluid of a pleasant yeasty odour, which had a specific gravity of 1·0416. On heating it a coagulum began to appear at 35° to 40° C., and on boiling the fluid assumed a semi-solid consistence. Buchner considers that the fermentative action is probably caused by an enzyme present in the yeast extract, but this he has not yet been able to isolate. W. J. S.

THE ANALYST.

MARCH, 1897.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, February 3, in the Chemical Society's Rooms, Burlington House, the President, Dr. Bernard Dyer, occupying the chair.

The minutes of the previous meeting were read and confirmed.

The following gentlemen were proposed for election: as members—Mr. John C. Candy, B.A., B.Sc. (Lecturer on Chemistry at the London Hospital); Henry de Mosenthal, F.I.C. (Chemist to Nobel's Explosives Company); John H. B. Jenkins, (Chemist to the Great Eastern Railway Company); Fredk. W. Harris (Public Analyst for the Borough of Burnley, Lancs.). As associate—Edward Halliwell (assistant to Mr. T. Fairley, Leeds).

The following gentlemen were elected associates of the Society: Arthur French Angell (assistant to Mr. Arthur Angell); W. H. Jackson (assistant to Mr. A. C. Wilson); Arnold Rowsby Tankard (assistant to Mr. A. H. Allen).

The following papers were read:

"Some Analyses of Water from an Oyster Fishery." By Charles E. Cassal.

"The Composition of Meat Extracts and Similar Products." By Otto Hehner.

"The Distillation of Formaldehyde from Aqueous Solution." By Norman Leonard, B.Sc., Henry M. Smith, and H. Droop Richmond.

"Remarks on Formaldehyde." By Charles E. Cassal.

THE ANNUAL DINNER OF THE SOCIETY OF PUBLIC ANALYSTS.

This took place, after the annual meeting on January 13, at the Criterion, under the chairmanship of the newly-elected President, Dr. Bernard Dyer. About eighty members and guests were present, amongst the latter being Mr. T. H. Elliott (Secretary of the Board of Agriculture), Professor Thorpe, F.R.S., Mr. Hudson E. Kearley, M.P., Mr. A. G. Vernon Harcourt, F.R.S. (President of the Chemical Society), Dr. W. J. Russell, F.R.S. (President of the Institute of Chemistry), Mr. J. Fletcher Moulton, Q.C., F.R.S., Professor H. E. Armstrong, F.R.S., Professor J. Millar Thomson, Professor Dunstan, F.R.S., Professor Meldola, F.R.S., Mr. C. E. Groves, F.R.S., Mr. Walter Hills (President of the Pharmaceutical Society, Dr. Messel (Chairman of the London Section, Society of Chemical Industry), Mr. A. C. Tanqueray (President of the Institute of Brewing), Mr. Aubrey Rake, Mr. A. B.

Gripper (Secretary of the London Corn Trade Association), Mr. W. P. Ricketts, Mr. J. Innes Rogers, Mr. G. C. Barnes, and Mr. F. W. Beck.

The CHAIRMAN (Dr. Dyer), in proposing the toast of "The Queen," said that wherever that toast was drunk this year it would be received with special enthusiasm, on account of the fact that Her Majesty was now completing the sixtieth year of her reign. It was pleasant to remember that for more than one-third of that long period the members of this Society had been able to drink this toast together, and there were, he believed, one or two present besides himself who had been present on every one of these annual occasions. This year the toast would be drunk with even more enthusiasm than in the past, and he sincerely trusted that it might be many years yet before any change was required in the formula in which Englishmen expressed their loyalty (applause).

The CHAIRMAN, in proposing "The Houses of Parliament," said he would venture to linger somewhat longer over this toast, because, owing to the special circumstances of the past year, he regarded it as the toast of the evening. They had been looking forward to the honour of having with them the Earl of Winchilsea, but he was very sorry to have to tell them that he had received a telegram from Lord Winchilsea from Hastings, regretting at the last moment that his health did not allow him to travel up to town. Lord Winchilsea was a nobleman who was well known throughout this country for the sympathy which he had with distressed agriculture, and, he might add, for the untiring energy with which he expressed that sympathy in a practical form by doing all that lay in him to assist the cause of the suffering farmer. Had Lord Winchilsea been present that evening, he (the speaker) was sure they would have had from him, in reply to the first part of the toast, a speech to which they would have all listened with very great interest. They had, of course, no politics in that Society. No doubt many of them had individual views, and differing individual views, on such subjects as the fiscal policy of this country; but there was one form of protection about the justice of which every one of them was agreed, and that was protection for the British farmer against unfair competition in the way of adulterated food products. Upon them, as public analysts, largely devolved the duty of enforcing that protection, and it was to show his sympathy with them in their work that Lord Winchilsea was good enough to promise to come to them that evening. They were sorry that he was ill, and they were sorry to miss his speech. They had present a well-known member of the House of Commons, whose name would be received with enthusiasm, namely, Mr. Hudson E. Kearley. Mr. Kearley was a distinguished representative of English commerce, and his efforts towards the improvement of the Food and Drugs Acts were known to them all; and they had lately been allowed to do themselves honour by recognising these efforts in electing Mr. Kearley an honorary member of that Society. They also had present Mr. Fletcher Moulton, who had served his country well in the House of Commons, though, owing to the fortunes of political warfare and to the indiscriminating caprice of his constituents, he was at present taking a temporary—they hoped only a temporary—rest from his Parliamentary labours. It was hardly necessary to remind the company that a large and very representative committee of the House of Commons had sat for the last three sessions to consider in what direction their food legislation

might be modified or reformed. That committee had collected a vast mass of evidence, to which that Society had—he thought he might say without boasting in the presence of their guests—made very valuable contributions, partly through individual members, but more especially as a Society through the mouth of their valued and very honoured and hard-working Past-President, Mr. Otto Hehner; and he would here say that he was very pleased to be able to take this opportunity of publicly thanking Mr. Kearley for the very great assistance which he had given to them during that inquiry, in enabling them to put their evidence before the committee in a satisfactory manner. This committee had now made a very full and very valuable report. There might be minor details in that report with which they could not all personally agree; he would not go into this, for the retiring President, Dr. Stevenson, in the very able address which he gave them that afternoon, had carefully gone through that report and discussed it, he might almost say, clause by clause. But he was sure he might say, leaving aside the details, that their Society was, broadly and practically speaking, in cordial agreement with the recommendations of the committee, and, in the presence of a representative of the House of Commons, he ventured, on behalf of the Society, to express the hope that the recommendations of that committee, or many of them, might be speedily transformed into law. They were most anxiously looking out for a new Bill, and when that Bill found its way into Parliament, they would look to Mr. Kearley and to their other friends there to help them in carefully watching the Bill; to consider any suggestions which they as a Society might possibly have to make on it, and to see that no amendments might be introduced into that Bill which might even remotely threaten to lessen its efficiency, without thorough discussion and thorough consideration. He thought he was not saying too much when he said that they, as public analysts, had done a great deal of good work in the past; they hoped to do better work in the future, but they could not do this unless the legal and administrative machinery underwent some improvement. For this improvement they were now looking to Parliament, firstly, for the sake of the food consumer, the great public; secondly, for the sake of the honest trader; next, for the sake of the British farmer; and he might say, finally, for their own sakes as officers who wanted to do their duty in as thorough a manner as possible.

Mr. Hudson E. Kearley, M.P., said he was glad to have the privilege afforded him of responding to this toast, if only for the opportunity of thanking the Society of Public Analysts for the great honour they saw fit to confer upon him last year by electing him an honorary member of their distinguished body. He desired to say that he appreciated that distinction highly, and any work that he might have done that seemed, in their estimation, to have entitled him to this consideration at their hands, he was sure had been a work of pleasure, and the honour they had paid him in conferring this distinction upon him had been far more than any endeavour of his had deserved. He regretted that he was alone in replying to this toast. He would have liked to have heard the Earl of Winchilsea respond before himself for that august body of which he was a member, but he would have been especially interested in hearing him relate his experience, and the result of the contest that he had been carrying on with a great amount of success on behalf of distressed British agriculture. He would, no doubt, have referred to the necessity that he felt to exist for some amendment of the

laws, in order that agriculturists might be protected from what the Chairman had called unfair competition. He would, no doubt, in following Lord Winchilsea, have said what he was going to say now—that although this question of adulteration was a question that materially affected agriculture, it was not only an agricultural question, but a question that affected the commercial interests of this country outside the agricultural interest, largely—more largely, indeed, in his opinion, than it affected agriculture. Still, it was encouraging to find that there was a body of men like the analysts of this country looking forward, as those interested in commerce were, to some amendment of the law, in order that they might be protected from the unfair results that arose owing to the inefficiency of the present laws. The past year, in a Parliamentary sense, had been an important one to the Society of Public Analysts. It had been important by virtue of the fact that the committee for which the Society had been working so long, and the appointment of which was mainly owing to its efforts, had issued its report. He agreed with the Chairman that that report did not contain all that they might have wished, but still, he believed that it would mark the commencement of a new and brighter era, not only for the commercial interests of the country, but for the public analysts, who had felt, more directly, possibly, than had the other bodies interested in this subject, the handicapping conditions under which their professional work was carried out so long as the law remained in its present unsatisfactory condition. They were all looking forward to some harvest as the result of their efforts. Those efforts had been long and arduous, and at times some friction had arisen between the views as expressed by the public analysts and those who differed from them; but now the committee had reported they were naturally expecting to get some satisfaction in the shape of a Bill which they hoped would ultimately become an Act of Parliament. He would suggest that the Bill they hoped to see introduced should be one to supersede all the Acts of Parliament at present on the statute-book dealing with the subject of adulteration. Personally, he would hope to see an Adulteration Bill introduced that would cover the whole field, and not leave them, as they were now, with one measure to deal with one article only, another measure to deal with food and drugs—and only partially with those; but that they would have a comprehensive, intelligible measure, that analysts could understand, that traders could understand; and he might go further—that the judiciary of the land could understand also. He had said that this committee had led to some differences of opinion, some of which, no doubt, were very strongly expressed; but he thought everybody was agreed that the best policy to pursue now was to bury all differences and look forward to the happy days that appeared to be in front, subject to this Bill being introduced. The most important recommendation of the committee, so far as concerned the public analysts, was that there should be set up a court of reference. It would be almost impossible for any satisfactory outcome to arise from their endeavours unless certain vexed questions were to be settled from time to time by such a court of reference. He did not believe it was possible to put into an Act of Parliament everything that was needed by the commercial interests and the public analysts on some of these vexed questions. Taking, for instance, the question of standards: the very moment one suggested a standard one was met by the objection on the part of others that if a standard were set up it inevitably meant that every-

body in the country lowered their goods down to this standard. There was something to be said for that. But if they had this court of reference they would have, he hoped, a competent body that would be fully alive to the necessity of keeping pace with the adulterations that might spring up. It had been his pleasure and privilege on the committee to examine, on behalf of the public analysts, many of their witnesses. He might say that the witnesses they submitted to the committee were experienced men, and naturally highly intelligent. His friend Mr. Otto Hehner he would almost describe as a model witness. He was so full of information that a special Blue-book might well have been devoted to his evidence. Mr. Hehner favoured the committee with most excellent evidence, and he (the speaker) was sure that if they succeeded in putting into an Act of Parliament only one-half of his recommendations, they would have a very progressive Act indeed. He did not propose to go through the various recommendations of the committee, but as he was in the presence of two or more representatives of Government Departments, he was obliged to give expression to this thought, that they did really require a Government department to look after the interests of this question. At present they had the Board of Agriculture, a body that, as was pointed out before the committee, was interested mainly in the question as it affected agriculturists; but he did think that no particular interest should be singled out for preferential consideration, but that the whole of the interests involved—those of the agriculturist, those of the trader, and, above all, those of the consumer—should be considered together. It was difficult to suggest what that department should be, because each department, in its particular work, no doubt did yeoman service on behalf of its particular interest; but it appeared to him that it would be most advantageous if they could commit the responsibility of administering the new law, which he believed would be passed, to a department which made the question of adulteration a leading feature of its departmental work. It had been heard in evidence that the local authorities were very remiss in some districts in working the existing Acts of Parliament. It had been said that the amount of adulteration that was found, from samples that were analysed, bore a definite relation to the amount of activity that was exerted by the local bodies. They had been told that so few samples were taken in many districts that the present Acts were practically allowed to be a dead letter. He knew that the public analysts thought—and he himself certainly agreed—that it was necessary that some central authority should be responsible for seeing that these Acts were efficiently administered, but he regretted to say that the committee could not come to a favourable decision on that point. It was pointed out that it would be very difficult for a central authority to undertake the responsibility of seeing that the Acts were actively administered, and he supposed there was no going back on the recommendation of the committee in that direction, but, nevertheless, he did venture to hope, as he had already said, that to one Government Department would be entrusted the responsibility of working these Acts on behalf of all the authorities concerned. Any movement in this direction must, he thought, tend to be beneficial to all concerned. The various recommendations of the committee would be of service in drawing up a new Bill. He could not say, even unofficially, that they were to have a new Bill, but he could answer for this, that if the Government did not

recognise their work, and did not introduce a Bill, there were certain of them that were interested in this question who were prepared with a Bill which, he thought, would meet the views, at all events, of the great majority of those present. Personally, he was looking forward with some amount of interest to the declaration of the Queen's Speech. He thought that this subject was sufficiently important to entitle it to some recognition immediately Parliament opened, and, without in any way holding out any threat to the Government as to the action that would be taken, he thought that if the Queen's Speech did not show some recognition of this question by an expression of the intention of the Government to introduce a Bill, someone would be prepared to ask the reason why. Individually, he would desire to say this: that they recognised the position of the Government as rather more difficult than their own, for they themselves were in a position of no responsibility, and consequently had greater freedom. The Government, on the other hand, naturally had to be somewhat guarded in its action upon such a question, but he hoped that the Government would see its way to an early opportunity of introducing such a Bill as was wished for.

Mr. Hehner, in proposing the toast of "The Various Government Departments," said he believed there was no public officer who had relations with so many Government Departments as the public analyst. He was appointed by a County Council, and was nominally a County Council officer, but he was under the control of the Local Government Board; he had to look to the Inland Revenue Department for control; he had to report, in his character of district agricultural analyst (which meant as a public analyst under the Fertilizers and Feeding Stuffs Act), to the Board of Agriculture; and, if the recommendations of the Food Products Adulteration Committee were carried into effect, he would also in the near future have to do with the Board of Trade. In one way this extensive connection with Government Departments was a testimonial to the usefulness of the public analyst as an officer, but it was not without its dangers. One man had only a certain value, and if this one man was split between five authorities, the proportion of his total value allotted to each might be but small.

There were present the representatives of two important Government Departments with which public analysts were connected. It was not the first (and, he trusted, would by no means be the last) occasion upon which the members of the Society had had the honour and pleasure of seeing among them Mr. T. H. Elliott, the Secretary of the Board of Agriculture. Public analysts ought to be (but unfortunately were not always held to be) of importance, and ought to be of use to the agriculture of this country, not only in contending against illegitimate home and foreign competition, but in stimulating scientific agriculture in many of its aspects. The public analyst should have been in past years in a position to exercise a useful influence in raising the standard of production of agricultural produce of all kinds, and also in relation to many scientific questions in which the agriculturists of this country were concerned. Unhappily, however, this had not been so altogether in the past, but they could look forward in the future to receiving able assistance from the Board of Agriculture. A great many public analysts were also district analysts under the Fertilizers and Feeding Stuffs Act, but they had not been able to be of much use in this capacity; but they looked forward, however, to an amendment that would increase the efficiency of the

Act, which, although well meant, had been lying, practically speaking, dormant. He thought he was rightly informed that the time was not far distant when an amendment would be introduced which would render the Act not merely a paper Act, but a really practical, workable measure.

As to the Inland Revenue Department, with which public analysts were so closely connected, he welcomed, in the name of all his colleagues, both present and absent, Professor Thorpe. It was particularly agreeable to him, for reasons which he need not specify, to greet Dr. Thorpe, and to extend to him the hand of friendship. They looked forward to an entirely amicable relation between public analysts and the Somerset House authorities under the *régime* of Dr. Thorpe, at whose service the experience of all public analysts would most gladly be placed. Nothing better was desired for public analysts than a close friendship with the Department which Dr. Thorpe represented. This friendship must be based, not only upon a unity of professional interests, but also upon a common desire to be of use to the country, and a mutual wish of scientific men to work hand-in-hand with one another.

Mr. T. H. Elliott said that he rose with the greatest pleasure to respond to the toast which had been so generously proposed by Mr. Hehner. He felt obliged to confess that when he received the invitation with which he had been favoured, he felt some hesitation as to whether he was justified, after so short an interval, in again accepting the hospitality of the Society. But when he heard that Dr. Dyer, a distinguished agricultural chemist, would occupy the position of president, he could not possibly resist the pleasure of supporting him in the chair, and of again meeting the members of their Society. The Board of Agriculture had heard of Dr. Dyer's elevation to the chair of the Society with very special pleasure, on account of his intimate association with agricultural interests during so many years. With reference to the toast which had been proposed, he could not but feel that there was a great community of interest between the Government Departments and the public analysts. They were both the servants of the public; they worked under very similar conditions, and he felt, from what he had read, that the atmosphere of criticism in which Government Departments lived was also freely breathed by public analysts. Reference had been made to chemistry in connection with agriculture. Chemistry had revolutionized the practice of agriculture in this country, and he thought that no agriculturist could look a chemist in the face without a feeling of gratitude for the great benefits which agriculture had derived from that science. Analytical chemistry was of especial interest to agriculturists, and in this connection he was glad to say that the number of analyses made under the Fertilizers and Feeding Stuffs Act was steadily increasing. In the first year during which the Act had been in operation 444 analyses were made; in the next year 615; and in the three-quarters of the year 1896 for which returns had been obtained, the figures of 1895 had already been beaten with 673 analyses; so that the services of public analysts had been called upon more frequently in 1896 than in any year since the passing of the Act.

Agriculturists, too, were not only consumers but also producers. Mr. Kearley had already referred to the special interest which the proceedings of the Food Products Adulteration Committee possessed for agriculturists, who were strongly

represented on that committee, and the Board of Agriculture, and agriculturists generally, owed a debt of gratitude not only to the committee, but to the witnesses who gave evidence before it. He had no authority to speak with regard to future legislation, but he entirely agreed with the view that it would be very desirable that they should have one Act in a convenient and easy form, and he hoped that the passing of such an Act would be shortly followed by the publication of a similar text-book to that for which Dr. Dyer was responsible when the Fertilizers and Feeding Stuffs Act was passed. Both as consumers of manures and feeding-stuffs, and as producers of agricultural products, agriculturists appreciated the services of Public Analysts, and they regarded the Society with the most friendly feelings, because, by the contact of thought with thought which was rendered possible by means of an institution such as theirs, an increase of scientific knowledge and skill was secured. Agriculturists wished the Society every prosperity, believing that such prosperity would be to their mutual advantage, and he was glad to have this opportunity of expressing his gratitude to the Society, and of most heartily wishing it every success in its labours.

Professor THORPE, F.R.S., hoped he would not be misunderstood when he said that he rose with considerable reluctance to return thanks on behalf of the Government Department with which he was connected. His reluctance sprang from the memory of the circumstance that scarcely twelve hours had elapsed since he had had an amicable passage of arms with the President, in which he had been worsted as to the propriety or necessity of what he might term "double-barrelled" speeches. It seemed to him (Professor Thorpe) that when a gentleman so eminently capable as Mr. Elliott of responding for the honour done came forward to perform that duty, nothing more remained to be said. He had a theory, in which he thought he was not singular, that public officials should be like the proverbial good little boy—they might be seen, but should not be too much in evidence. Still, in some respects he might perhaps lay claim to a certain prescriptive right to a share in the response for the various Government Departments, because there were few officials who came into contact with so many of these Departments as he himself did. Indeed, he felt himself, to paraphrase the well-known saying, to be the servant of all and the master of none. The Government Laboratory not only served the Inland Revenue and Customs Departments, but the Board of Agriculture, the Board of Trade, and the Home Office, the War Department, the Admiralty, the India Office, the Local Government Board, and the Post-Office—in fact, he ventured to think there were few Government Departments that did not in some way or other call upon the services of the Government analysts.

Some allusion had been made to a matter in which he naturally took a considerable amount of interest, viz., the work of the committee which had just reported, and from whose endeavours so much was naturally expected. He had read with considerable interest and with very great profit the exhaustive statements contained in the evidence which was brought before the committee, and he might say in a word that with the general conclusions of that report, and especially that section of it which might be considered to affect himself more than any other section, he was entirely and wholly in agreement. The suggested Consultative Board, or Board of

Reference, would be, to any man charged with the duties and functions which he (the speaker) had to perform, a very great boon. The old Adulteration Act was of course a thing of compromises, and it bore upon its very face the evils of compromises. In the administration of that Act a great many difficulties arose which had to be solved in the best way that was open, and in a way which, it must be admitted, when all was said and done, could not be wholly satisfactory. With regard to the question of standards, he might say that at the Government Laboratory they had no legal power whatever to fix standards. The question of standards was a difficulty which was of course constantly arising. Now, the Board of Reference which was spoken of might, he hoped, not only solve this question, which was an extremely knotty one, but many others of interest and importance both to the public analysts and to the Government analysts. Mr. Hehner had more especially alluded to him (Professor Thorpe), and had been good enough to extend, in his characteristic manner, what might be called the right hand of friendship to himself personally. He had already said, upon a previous occasion of a similar nature, and he repeated it, that it was his earnest desire that those at the Government Laboratory should work in perfect harmony with this Society, as representing the great body of public analysts. How this object might best be accomplished was of course a matter to some extent to be determined by the operation of the Bill that was in prospect; but he could not help thinking that those little points of difference (which after all were perhaps not of a very grave nature) would be materially smoothed away by that personal association and friendly discussion which the proposed Board of Reference would inevitably bring about; and therefore, speaking for himself, and he thought he might add for those also with whom he was associated in the work of the Government Laboratory, he agreed most cordially with the suggestion that such a Board should be appointed.

Dr. J. A. Voelcker, in proposing the toast of "The Learned and Professional Societies," said that his mind had been exercised during dinner as to what distinction might properly be drawn between "learned" societies and "professional" societies, but with the help of a neighbour whom he would not specify, he had been able to apply a definition which fairly commended itself to him. It was that a learned society was a society which existed for the advancement of knowledge, while a professional society was a society which existed for the advancement of the individual. Both of these two branches he wished to couple together in the toast which had been allotted to him. Although the Society of Public Analysts was perhaps not so much a learned as a professional society, it must be felt by public analysts that as their work became more and more important, so also it became more and more important that the true principles of science should be thoroughly grounded in them. They would welcome, therefore, the presence among them of Professor Vernon Harcourt, F.R.S., the able representative of the Chemical Society, whose work in a scientific direction was particularly distinguished. They had also the honour of meeting Dr. W. J. Russell, F.R.S., the President of the Institute of Chemistry, and he (the speaker) was sure that public analysts especially would appreciate the efforts made by that Institute, not only under its present President, but also under those who had gone before him, to give to the chemical profession a

proper standing in the eyes of the public. It was a very pleasing reflection that many members of the Society of Public Analysts were also members of these two societies, and of others which were represented on that occasion, namely, the Pharmaceutical Society, the Institute of Brewing, and the Society of Chemical Industry, etc. As to their own Society, although, as he had said, it was perhaps not a learned Society in the stricter sense of the term, still he thought it might claim to be progressing in its learning. It numbered among its members members of some of the most distinguished societies which existed for the advancement of science, and he hoped that its work in aiming at strengthening the public analyst's position and enabling him to grasp and retain the confidence of the public, would be successful and would meet with general approval.

Before concluding, he would like to remind the members of the Society of the fact that, by the kindness of the President of the Chemical Society and his predecessors, their meetings had been allowed to take place in the Chemical Society's Rooms for the last two-and-twenty years; a similar recognition was also due to the President of the Institute of Chemistry, the rooms of that Institute having also been placed at the disposal of the Society upon several occasions.

Mr. A. G. Vernon Harcourt replied, remarking that he could hardly agree with Dr. Voelcker in the distinction he had drawn between a learned and a professional society. There were men who studied chemistry purely in the interests of science, and there were busier—and perhaps more useful—men, whose work lay in the direction of the practical applications of science.

In a pleasant volume of stories written by Mr. Andrew Lang, there was one which bore the title of "The First Radical." The principal character was named—in accordance with the fondness of savages for repetition—"Why-Why." He was a gentleman who never took things as he found them, but always asked for causes. He seemed, in fact, to be a sort of incarnation of the scientific spirit. It might, perhaps, be doubted whether the scientific spirit had not gone too far in this direction, and whether men were not sometimes too anxious to arrive at causes (even to guess them if they could not find them out) rather than to content themselves with the humbler search after facts. But this impatience, this desire for increased knowledge of Nature, the impulse to observe a new fact, to look into it, to inquire "What is it?" "Will it happen again?" "What is the cause of it?" that really was the basis of all scientific inquiry; and its value as a part of human nature was inestimable. This spirit of investigation, for which we had no better name than curiosity or inquisitiveness, this sort of instinct which existed, by no means, he was afraid, in all men, but certainly in many—probably in all who were present on that occasion—and also, he thought, in all children; this impulse to try and find out about things, had been of much service to humanity. The increase of knowledge to which it had led had benefited humanity, for it was the necessary precursor of those technical applications of science of which the utility was obvious. No doubt a good deal of the public support which science received depended upon a well-founded impression that science, somehow or other, however uninteresting it might in itself appear, was of benefit to mankind.

There was another aspect of this question, namely, the change of opinion as to

the universe around us, which had been brought about by increased scientific knowledge. The relation of this world to other worlds, the relation of men themselves to other men and to all other living things, had been cleared up by the investigations which had sprung from this desire for knowledge; and if they compared themselves, as perhaps with some just complacency they might, with at any rate some of the previous generations, it might be justly claimed that to this different way of looking upon the world were due the advances that had been made.

One of the chapters in a well-known book by G. H. Lewes, "The Physiology of Common Life," began with a panegyric on hunger. It was the chief motive power of humanity. Men engaged in their pursuits put out what energy they did put out because of this imperious craving. It seemed to him that those were especially happy in whom this general necessity of nature—the need of earning the means of subsistence—could be satisfied by satisfying at the same time the other craving for fuller knowledge. All of them—whether members of learned societies who were engaged in teaching, or those who, having a knowledge of science, applied their knowledge in dealing with legal questions or as public analysts—all had the advantage of satisfying at the same time these two desires, the desire to know, and the desire for the means of living.

He could not quite agree with his friend Dr. Thorpe in his expression of regret that there should be "double-barrelled" speeches. There were many topics to which he might have referred, but which he was glad to be able to leave in the hands of Dr. Russell. He had spoken of the origin and nature of the scientific spirit, and the advantages it conferred upon those in whom it existed, and upon humanity generally; but he had said very little about the learned and professional societies. The reason why men gathered themselves together—whether to hear papers read and to discuss them, or upon such pleasant occasions as that particular one—was perhaps some gregarious instinct; but there was one very practical and obvious reason for their so doing, and that was the advantage to be gained by combination. It was perhaps fortunate for the Chemical Society that it very rarely needed to approach any Government Department, but in another learned society with which he was connected, viz., the British Association, appeals on behalf of science were made from time to time, and the advantage of combination at once became apparent. He thanked them on behalf of the Learned and Professional Societies.

Dr. W. J. Russell also responded, remarking that chemistry could probably claim, and indeed required, a larger number of really active societies than any other branch of science. The work which these societies had to do rendered it necessary that they should stand shoulder to shoulder in order to carry it on, and all small jealousies between them ought absolutely to be (and he believed at the present time were) annihilated. In expressing his sense of the honour done him in asking him to respond to this toast, he could only say that he believed the Society which he then represented was most honestly and fully deserving of all honour. It did its best to maintain a high professional standard, and admitted into its body only those who could prove they had undergone a lengthened course of study, such as to fit them to be chemical advisers.

Dr. Armstrong, in proposing "The Society of Public Analysts," said that those

who were present had been brought so intimately into connection with the Society as not to require much information concerning it. He personally had long taken a great interest in its proceedings, for shortly before it commenced work he came into office as one of the Secretaries of the Chemical Society, and in that capacity had had every opportunity for taking notice of what the Society of Public Analysts had done. It had now attained its majority, and full information regarding its history up to that point was contained in the admirable presidential address which Dr. Stevenson had delivered to its members some twelve months since. When one looked at the progress that had been made in chemistry during those years, the increase in our knowledge appeared marvellous, and altogether out of proportion to anything attained in any previous period; but he thought he was justified, not only in saying that the progress of the Society of Public Analysts had been entirely proportional to the progress made in the science of chemistry, but also in claiming for the Society a very high position among kindred institutions throughout the world. The public analysts had rendered very valuable service in connection with milk, an article specially important from the fact that young children were fed upon it during the earliest years of their lives; but he did not feel altogether happy when he heard standards mentioned, and was very glad to know from Professor Thorpe that his department, at all events, had no fixed standard; a fixed standard undoubtedly had the effect of raising the quality in some cases, but in a far larger number it resulted in diminution of quality. Only a short time since he had seen an article in the Journal of the Pasteur Institute, arguing that there should be no fixed standard in the case of an article of food like milk. There was another point, namely, the use of preservatives. It was not likely that they could get into the stomach without producing some effect, and the growing use of formalin and of boracic acid, especially the latter, ought to be stamped upon by public analysts. Even if the Society's work had been confined to the subject of milk, its existence would have been justified—but it had done an immense deal more than this. It was very important that they should not confine themselves merely to the carrying out of the technical details of food and drug analysis, and this had been fully recognised by the leaders of the Society. Men like Allen, Dupré, Dyer, Hehner, and others, had shown that the body was not merely engaged in professional duties, but was also occupied in advancing the science of chemistry. Mr. Allen had done immense service by his wonderful book on "Commercial Organic Analysis." Dr. Dupré and Mr. Hehner had given to the world most valuable methods of analysis; and he was sure that the Secretary of the Board of Agriculture would be interested in knowing of the method for measuring the fertility of soils which had been devised by the new President of the Society, Dr. Dyer. With the toast he was proposing he desired to couple the name of Dr. Stevenson, who was a very honoured member of the Society. Dr. Stevenson and he had had occasion to work together for many years in the Chemical Society, and he could say, from his own experience and from that of all his colleagues in the Chemical Society, that Dr. Stevenson was a man worthy of the utmost respect in every way. His dignity of manner, his sobriety of judgment, were well known, and he had done yeoman service on behalf of the Society of Public Analysts during the two years he had been its President. It therefore afforded him (the speaker) great pleasure to couple Dr. Stevenson's name with this toast.

Dr. Stevenson said it was with a feeling of pleasure that he rose to respond to this toast, and he had especially to return his grateful thanks to his old friend Dr. Armstrong for the warm terms in which he himself had been referred to. He had been anxiously looking out for any adverse points which might arise in Dr. Armstrong's remarks with regard to the Society of Public Analysts, for it was well known that Dr. Armstrong, although a warm friend of all science, was yet one of the keenest critics of analytical chemistry; but there were no such adverse points, and this would be esteemed a great honour by anyone who knew Dr. Armstrong.

He (Dr. Stevenson) was one of the founders of the Society, and was its earliest Treasurer. Looking back upon the period of two and twenty years that had elapsed, he felt that the Society was to be congratulated on the advances it had made. Like all progressive societies, it had undergone a good deal of adverse criticism, but, nevertheless, it now comprised most of the important analytical chemists in the kingdom.

Mr. Cassal said that the task which he now rose to perform was an easy and most pleasant one, since it was the proposal of the health of the guests who had honoured the Society with their presence on that occasion. The list was a long one. Dr. Thorpe, the head of the laboratory at Somerset House, they received with the same cordiality that they had ventured to extend to him last year. And they did so not without the hope that in the future the atmosphere that surrounded Public Analysts and the Analysts at Somerset House might be less heavy with thunder-clouds and less seamed with lightning-flashes than it had been in the past. Mr. Elliott, the Secretary of the Board of Agriculture, was also present, and had told them (if not in actual words, at least in spirit) that in the future the working of the Fertilisers and Feeding Stuffs Act would result in the awarding of princely emoluments to those who had the honour to be District Agricultural Analysts. Then they had with them the President of the Chemical Society and of the Institute of Chemistry, and Mr. Fletcher Moulton, with whose name he would couple the toast, and with whom many of them were well acquainted. He believed that in the ante-room that evening either Mr. Moulton or Mr. Ricketts, who was also one of their honoured guests, had been asked the reason of his presence at a gathering of Public Analysts. He thought that all those who had been in a witness-box before Mr. Moulton or Mr. Ricketts would know that the presence of both those gentlemen among Public Analysts was singularly appropriate. He could testify that they were both masters of the art of analysing analysts. The President of the Pharmaceutical Society was also present; the Chairman of the London Section of the Society of Chemical Industry (Dr. Messel); the President of the Institute of Brewing (Mr. A. C. Tanqueray); Mr. C. E. Groves, the valued Editor of the Journal of the Chemical Society; Mr. J. Innes Rogers, a distinguished member of the London Chamber of Commerce; Mr. Beck, a gentleman whom some of the members had met in connection with the settlement of various knotty questions; and many other visitors, in regard to whom he might say that they were all in every sense worthy visitors of the Society of Public Analysts. He asked the members of the Society to drink to the health of those who had honoured them by their presence, and by their

way of doing so to assure them that the Society of Public Analysts received them in all cordiality and with the greatest pleasure.

Mr. J. Fletcher Moulton, in responding, said that he was somewhat surprised that this task should be accorded to him, but he had come to the conclusion that he had been selected as being probably the most remarkable instance of conversion in favour of the support of public analysis. He had to make the confession that he started in early life with a strong prejudice in favour of adulteration. This might perhaps seem somewhat original, but it must be remembered that the history of every man largely depended upon the circumstances of his childhood, and one of the earliest things he could recollect himself was wandering into the laundry and discovering there some poisonous compound which was used in those regions, and which, with that generalizing faculty so characteristic of children, he immediately applied to the purposes of food. The doctor, when sent for, was somewhat astonished to find that the expected symptoms of poisoning had not set in with sufficient vigour, which he (Mr. Moulton) had always attributed to the fact that, even at that early age, his own radical ignorance of the manner in which chemical substances ought to behave had shown itself, and the substance, feeling itself out of place, had not taken the trouble to behave as it should; but his comforted parents were told by the doctor that, providentially, it was a highly-adulterated article. Under these circumstances it was not unnatural that he should start in life with a prejudice in favour of adulteration. It had been his fate, not once or twice, but often, to be accused of appearing in defence of such atrocious practices. The last occasion of this kind that he could remember was in 1881, when he was before a Parliamentary Committee on the subject of the electric light, and had put Sir William Siemens into the box, and had examined him. A very worthy counsel—the representative of the united gas companies—got up and said in a tone of deep solemnity: "Dr. Siemens, electricity is but a young science. Now, Dr. Siemens, will you tell the Committee whether we have got far enough to protect the public against adulteration?" Dr. Siemens had the wit to say that the only instance of adulteration of electricity he had ever heard of was in connection with greased lightning! (loud laughter). He desired, however, having now forgotten the lessons of his childhood, to wish, on his own behalf and on that of his fellow-guests, increased prosperity to the Public Analysts.

Mr. W. F. Keating Stock proposed "The Editorial Committee of the Analyst," coupling with the toast the names of Dr. Sykes and the past presidents of the Society. Gratitude might, he thought, be described as of two kinds, "ancient" and "modern"; "ancient" gratitude being taken to represent a feeling of thankfulness for benefits already received, and "modern" gratitude a lively conception of benefits to come. Both kinds of gratitude would be felt by members of that Society in connection with the duties of the Editorial Committee, and of Dr. Sykes, who had devoted a very large amount of time and labour to the duties devolving upon him as editor.

The toast was briefly acknowledged by Mr. Allen, in the absence of Dr. Sykes.

Mr. Bertram Blount desired to submit a toast which, although not officially announced, would, he was sure, meet with cordial approval. It was the health of those permanent officials who did so much for the Society, though in such an unobtrusive way that their existence was sometimes in danger of being forgotten.

It was well known that the business of no body could go on smoothly without a great deal of work, which must be voluntary, and which might be dull. In submitting the toast of the officials, he would more particularly mention their new President, who for long had done excellent service as Secretary. The work of an official of this kind was not to be computed by the minutes he spent in the official gatherings of the Society; it meant a great deal more than that. It included work performed, very likely, at the expense of his own private occupations, and altogether severed from those cheering influences which surrounded public service. He would like, also, to mention the work of Mr. Bevan, who, in conjunction with Mr. Cassal, the newly-elected secretary, would carry on the secretarial business of the Society; and also their most admirable treasurer, Mr. E. W. Voelcker, who, as they knew, had been seriously ill, and was even now only partially recovered. They were happy to know, as he (Mr. Blount) had learned that evening, that Mr. Voelcker's recovery was going on as well as could be wished, and would, it was to be trusted, be rapid and permanent.

Dr. DYER, in rising to respond, said that there were good reasons why his acknowledgment of this toast should be a brief one. He had that day forfeited the right to reply for the Secretaries, and he had not yet earned the right to speak in the capacity of President. But he would not like to sit down without thanking the members of the Society, one and all, most heartily and most sincerely, for the honour they had done him in unanimously electing him to that chair; and he could only hope that when his term should have expired, he would have done one half of what their late good President, Dr. Stevenson, had done to earn the thanks of that Society.

FOOD AND DRUGS ANALYSIS.

The Critical Temperature of Dissolution. Application to the Analysis of Butter. L. Crismer. (*Bull. de l'Assoc. belge*, 1896, x., 312-316.)—In his several communications on the critical temperatures of dissolution (*cf.* ANALYST, xx., 209 and 257; and xxi., 241), the author has made the determinations in sealed tubes. It is now shown that when the critical temperature does not exceed 78° C., the boiling-point of alcohol, an open tube may be conveniently employed. About 0·5 c.c. of the filtered butter-fat is placed in the reaction-tube (which is 7 to 8 cm. long and about 1 cm. in diameter), with about twice its volume of alcohol, which must be absolute, or nearly so. The tube is closed by a cork, through which passes a thermometer with its bulb entirely covered by the liquid, and not touching the sides of the tube. The tube and thermometer are gently heated in a larger tube, which serves either as an air- or water-bath, the contents being vertically agitated until they give a homogeneous liquid. They are then allowed to cool, and the temperature at which they become turbid is the critical temperature. The small amount of alcohol evaporating during the process does not materially affect the results.

In the following table the alcohol used had a density of 0·7967 at 15·5° C., and contained therefore 0·9 per cent. of water by weight. The dilute alcohol used for the

parallel determinations in sealed tubes had a density of 0·8195 at 15·5° C. (=8·85 per cent. of water). The figures under *a*, *b*, *c*, etc., show the results obtained on repetition after adding a little more alcohol.

When figures are obtained materially lower than those given here for butter, the author's experience is that they are either old and rancid samples, or fresh butters badly prepared from acidified cream. As was pointed out in a former paper (see ANALYST, xxi., 241-243), the lowering of the critical temperature is proportional to the acidity of a fat. By neutralizing such butters with a 10 per cent. solution of potassium carbonate, and washing the fat with hot water, the normal critical temperature is obtained.

It is a curious fact that the number of c.c.'s of alcoholic $\frac{N}{10}$ KOH required to neutralize 2 c.c. of butter fat in 20 c.c. of absolute alcohol, when added to the figure representing the critical temperature of the acid butter, gives approximately the critical temperature of the neutralized butter.

ORGANIC ANALYSIS.

On the Volumetric Determination of Starch by Means of Iodine Solution. Fannie T. Littleton. (*Amer. Chem. Jour.*, 1897, xix., 44-49.)—The object of this investigation was to determine whether small quantities of starch could be determined colorimetrically by means of the iodine reaction, as has been stated by several workers in this direction.

A standard solution of iodine was prepared, which contained iodine dissolved in potassium iodide in the proportion of 1 molecule to 1 molecule, and this was used in conjunction with a standard solution of wheat starch containing 0·1 gramme per litre.

Temperature was found not to have much effect when the rise was not more than 5° C., but above this the colour gradually became fainter, and almost disappeared when the temperature had risen to 15 degrees.

Potassium hydrate, when added to the extent of 0·002 gramme, caused 1 gramme of starch to dissolve rapidly, and did not affect the colour of the starch iodide solution if the alkali were exactly neutralized before the addition of iodine.

Solutions of various kinds of starch were then compared, an exceptionally pure specimen of arrowroot starch being taken as the standard, and the heights of the columns of corresponding colour being compared with this. The strengths (which varied inversely as the heights of the columns) were as follows: Arrowroot, 100; potato, 97·06; wheat, 94·81; tapioca, 90·41; and rice, 83·83. These results were about what one would expect from the known relative size of the starch granules. Hence, rice starch, with its smaller granules and consequently probable larger amount of cellulose, should not show as high a percentage of true starch as arrowroot with its larger granules. Experiments made to determine whether the quantities of starch and iodine required to produce the maximum colour had a definite ratio showed that this was the case. Thus 0·007 gramme of starch required 0·00448 gramme of iodine, and 0·001 gramme required 0·00064 gramme; but this only held good when a solution of iodine of a single strength was employed, for when the same quantity of starch solution was tested with iodine solutions of different strengths, the results were quite irregular. This was ascribed to the dissociating effect of the additional water contained in the weaker iodine solutions, and this view was confirmed by other experiments described in the paper. Therefore, in using the method, it will be necessary to compare substances whose percentages of starch do not differ widely.

It is further shown that chloroform will extract iodine from moist starch iodide, although the contrary is stated in Thorpe's "Dictionary of Applied Chemistry," iii., 565.

The general conclusion arrived at is that, on account of the easy dissociation of the so-called starch iodide, the method is only available with substances containing a large amount of starch, and the colorimetric comparisons must then be made under conditions very nearly identical. This limits very considerably the application of the process in the examination of food material, although in occasional cases it may be of value. C. A. M.

On the Purification of Phenyl-Glucosazone. L. Hugounenq. (*Jour. Pharm. Chim.*, 1896, 447, 448.)—Anisol ($C_6H_5.O.CH_3$) is substituted for acetone in the re-crystallization of the washed glucosazone. The impure osazone is washed in the cold with water, alcohol, and acetone, re-crystallized from hot anisol (B.P. 152-154°) and the crystals washed with dilute alcohol. They are then perfectly pure, and melt at 204°-205° C. The advantages claimed are that less solvent is required, and that the penetrating odour of acetone is avoided. C. A. M.

On the Messinger Method of Estimating Acetone. H. C. Geelmuyden. (*Zeit. anal. Chem.*, 1896, xxxv., 503-516.)—Messinger's method (*Zeit. anal. Chem.*, xxix., 696) consists in adding potassium hydrate to the acetone solution, then shaking with an excess of standard iodine solution, liberating the excess of iodine with hydrochloric acid, and titrating with thiosulphate. The author employed this method for the estimation of acetone in the breath and urine of animals, and having to work under very varying conditions, made control experiments to determine to what extent these influenced the accuracy of the results.

For determining the amount of acetone given off in the breath by rabbits a respiration apparatus, constructed on Pettenkofer's principle, was employed. The animals were enclosed in a cage through which a continual stream of air was drawn, which, on issuing from the cage, was divided into a main and branch current, both of which were mechanically measured. It was not possible to determine the acetone in the branch current by conducting this through a mixture of potash and iodine solution, since, as was shown by Collischonn, the mixture soon ceased to convert acetone into iodoform, and after half an hour became completely useless. But by passing the current through strong potash alone, all the carbon dioxide and a portion of the acetone were retained, which latter could be subsequently titrated. The air was then passed through a tube containing hot copper oxide, and the carbon dioxide produced was absorbed by baryta in a modification of Pettenkofer's tube (ANALYST, this volume p. 83).

Blank experiments proved that besides acetone no other volatile organic substance was given off in the breath of animals; and in other experiments in which weighed quantities of acetone were volatilized in the empty cage the amount found corresponded with that taken within from 5 to 10 per cent.

It was also proved that the strong potash required by this method did not have any decomposing influence on the acetone retained by it (at least within twenty-four hours), but before adding the iodine solution it was found necessary to dilute the liquid with from 2 to 3 times its volume of water, since, otherwise, the formation of the iodoform was so instantaneous that particles of iodine were mechanically enclosed.

In the Messinger-Huppert method of estimating acetone in urine a certain amount of loss appears to be inevitable, this loss, according to the author's experience, increasing with the amount of acetone present. In experiments in which only trifling amounts of acetone were added, the mean loss in five determinations was 6·75 per cent. of the total quantity added when the distillate was cooled with ice, and 8·30 per cent. when this precaution was not taken. Before adding the iodine solution

to the acetone distillate, the latter, when cooled with ice, should be raised to a temperature of 18° to 20° C. by the addition of hot water.

Since all normal urine contains traces of volatile substances which combine with iodine, a correction must be made for these. In the case of human urine this amounted to from 0·58 to 1·35 milligrammes, calculated as acetone per 100 c.c.

The addition of urea is not advisable, unless the urine under examination contains large quantities of nitrites, since the distillation, even without the addition, yields results which are too low, and the urea usually lowers the amount still further.

C. A. M.

A Contribution to the Chemistry of Animal Fats. C. Amthor and J. Zink. (*Zeit. anal. Chem.*, 1897, xxxvi., 1-17.)—While introducing no new methods, the authors have determined all the usual constants of the fat of a large number of animals and birds which, in many cases, had never been previously examined. Their mean results are given in the subjoined table, in which the Hübl number was determined by adding an excess of 50 to 60 per cent. of iodine, the Reichert number on 2·5 grammes of fat, and the acetyl number by the original method of Benedikt. The melting-point was taken in a capillary tube, closed at one end, and the two numbers given are respectively those of the commencement and end of the fusion.

* Two years in captivity.

Referring to the above results, the authors drew a number of general conclusions: In the case of tallow-like fats a high specific gravity of the fat was accompanied by a high melting-point and low iodine number. The iodine number of the fats and fatty

acids decreased on keeping, whilst, on the other hand, in the case of many fats, such as that of the stag, dog, and wild boar, the acidity number increased. The acetyl number of the fats also became greater with age. The iodine number, and generally the acetyl number, were lower in the fat of domestic animals than in that of the corresponding wild animals. Similarly, a difference was noticeable in the case of the birds, the fat of the domestic goose, hen, and duck being lard-like, whilst that of the related wild birds was oily.

In four cases the fats exhibited marked drying properties, three of them becoming quite solid in the course of seven or eight to twelve days when spread in a thin layer on a glass plate. This property was possessed by the fat of the hare, wild rabbit, wild boar, and, in a lesser degree, by that of the blackcock.

The fat of the wild boar differed from common lard in having a higher specific gravity, iodine number, and acetyl number, and especially in the above-mentioned drying property.

Fox-fat differed from that of the cat and dog in its higher iodine number and specific gravity, but more particularly in its high acetyl number; while the principal differences in the fats of the common and wild cats were the higher Reichert and acetyl numbers, and the considerably higher acidity numbers of the latter.

Polecat-fat was quite liquid, and showed somewhat lower constants than the fat of the marten. The fat of the dog and cat were very similar in appearance to lard, which they also resembled in analytical results, with the exception of the acetyl value.

Of the different bird-fats examined, that of the blackcock was noticeable for its drying properties and high iodine number. When spread in a layer on glass it gradually set to a varnish, which, however, still remained sticky. After fourteen days drying was still proceeding. After being dried for ninety-five days, the iodine number of the fat had fallen to 29·7. C. A. M.

The Separation of Alkaloidal Extracts. C. Platt. (*Jour. Amer. Chem. Soc.*, 1896, xviii., 1104.)—The persistent emulsions which frequently occur in the analysis of alkaloids, as, for instance, in the ether and benzene extractions by the Dragendorff method, may be separated in a few minutes by filtration through cotton-wool in the following manner: The filter tube, which is similar to a Soxhlet tube, is fitted through the cork of an Erlenmeyer flask, while a stout platinum wire, bent at the upper end, passes through the constricted portion of the tube to the bottom of the flask. Washed cotton is packed firmly in the tube to a depth of about 4 c.m., and the apparatus is connected with a filter-pump. After filtration the separated liquids may be carefully poured into a separating-funnel and treated in the usual way.

C. A. M.

Estimation of Caffeine in Tea, Coffee, etc. A. Delacour. (*Journ. Pharm. Chim.*, 1896, 490, 491.)—It is claimed that the following method is very rapid, and gives completely accurate results: Two grammes of the finely-divided substance are boiled in a 100 c.c. flask for 10 minutes with 80-90 c.c. of water; after cooling, 4 c.c. of basic lead acetate are added, the liquid made up to the mark, shaken and filtered.

The alkaloid contained in 50 c.c. of the filtrate is then extracted with chloroform in the usual manner and weighed. In the case of green tea or green coffee the caffeine is crystalline and colourless, but with roasted coffee it is slightly brown.

C. A. M.

The Assay of Fluid Extract of Coca. C. T. Kingsley. (*Amer. Jour. Pharm.*, 1896, lxviii., 609.)—Eight fluid extracts representative of those found in the market in the United States were examined. After preliminary experiments, Lloyd's process was found to give the best results. The green coloring matter was removed by dissolving the crude alkaloid in acidulated water and filtering; the solution was then made alkaline with ammonia, and the alkaloid extracted by shaking out with chloroform. In each assay 10 c.c. of the fluid extract were taken. The percentage of cocaine found varied from 0·335 to 0·675, the mean being 0·544. C. A. M.

The Separation of Codeine and Morphine. L. Fouquet. (*Jour. Pharm. Chim.*, 1897, xvii., 49, 50.)—This method of separation depends on the greater solubility of codeine in anisol. Pure anisol (specific gravity 0·991 and B.P. 152°) dissolves codeine readily in the cold, and its solvent power increases as the temperature rises. Morphine, on the other hand, is quite insoluble in cold anisol, and only slightly soluble in the boiling liquid. The following table illustrates this difference in solubility at different temperatures:

Temperature	0° C.	16° C.	32° C.	100° C.	150° C.
Morphine, per cent.	insol.	insol.	insol.	0 95	4·80
Codeine, per cent.	7·80	15·28	—	164·00	—

It is remarkable that the solubility of codeine is greater after it has been crystallized from anisol. Thus, after one crystallization the alkaloid dissolved to the extent of 10·75 per cent. at 0° C.

An experiment was made on a mixture of 1·044 gramme of codeine and 0·710 gramme of morphine. This was exhausted by trituration with 20 c.c. of anisol at 15° C., and the residue washed with an addition of 10 c.c. and dried. The amount of morphine recovered was 0·702 gramme. C. A. M.

Estimation of Nitrogen in Guanos, etc. V. Schenke. (*Chem. Zeit.*, 1896, xx., 1031.)—In consequence of certain criticisms on his past work, the author has reinvestigated three of the different processes that have been recommended for this analysis: (1) Förster's modification of Jodlbauer's process, (2) the Ulsch-Kjeldahl method, and (3) Haselhoff's plan of extracting the guano with water. The samples examined were 10 in number, consisting of natural guanos, mixtures of the latter with increasing amounts of sodium nitrate until they contained about 5 per cent. of nitrogen as N_2O_5, and ordinary commercial saltpetre, the total nitrogen present varying from 0·84 to 15·65 per cent.

The results obtained show that the Ulsch-Kjeldahl process always gives the correct yield of nitrogen; and that the Jodlbauer-Förster method is equally exact,

not only up to the limit of 2 per cent. of nitrate nitrogen, as stated by Franke,* but even when 5 per cent. is present. In two cases Haselhoff's process gave only 6·70 and 6·80 per cent. of total nitrogen, instead of 7·71 and 7·46 per cent. respectively; and further investigation showed that this deficit was due, not to "easily soluble organic nitrogen compounds" (Franke, *loc. cit.*), which expression can only mean ammonium oxalate, but to such substances as uric (or hippuric) acid and guanine. These latter, on distillation with caustic soda or reduction with iron and sulphuric acid (Ulsch), only yield from 2·7 to 11·8 per cent. of their nitrogen in the shape of ammonia.

Haselhoff's extraction process, therefore, gives satisfactory results when uric acid, etc., is practically absent; but it is not adapted for the analysis of guano and similar manures.

In the presence of much nitrous acid, both the Ulsch-Kjeldahl and the Jodlbauer methods return too little total nitrogen; it is consequently necessary in such cases to oxidize the substances first; but the author has not yet succeeded in elaborating a convenient plan for doing this. F. H. L.

INORGANIC ANALYSIS.

The Estimation of Cadmium as Oxide. By Philip E. Browning and Louis C. Jones. (*Zeits. Anorg. Chem.*, xiii., 2 and 3, p. 110.)—The authors have repeated Muspratt's methods for the estimation of cadmium as oxide, and show that the inaccuracies which he found, owing to reduction of the oxide, can be avoided, and the precipitation of the element as carbonate and conversion into oxide serves as a reliable method for the determination of cadmium.

The authors operated on quantities of cadmium sulphate corresponding to from 0·1140 to 0·2555 gramme cadmium oxide. They proceeded in the following manner: Weighed quantities of cadmium sulphate were dissolved in hot water, diluted to about 300 c.c., and a 10 per cent. solution of potassium carbonate was slowly added, and the solution shaken constantly, until no further precipitation took place; the solution was then boiled for fifteen minutes, and the precipitated carbonate converted into the crystalline form. The solution was then filtered into a Gooch crucible containing a layer of ignited asbestos, the precipitate, after careful washing, was dried, and heated to redness until constant. The authors show that the estimation yields reliable results, and that the process is much more expeditious than that proposed by Muspratt. The results are, however, liable to be a little too high, owing to the presence of small quantities of potassium carbonate.

H. C. L. B.

The Quantitative Estimation of Bismuth. By W. Muthmann and F. Mawrow. (*Zeits. Anorg. Chem.*, xiii., 2 and 3, p. 209.)—The authors show that bismuth can be accurately estimated, as such, by precipitation with hypophosphorous acid,

* Franke apparently referred to the original form of the Jodlbauer process (cf. ANALYST, xxi., 164), which the present author objects to on the ground of its being too tedious.—ABS.

and they state that their method in many cases exceeds, in accuracy and speed, those hitherto known. The experiments were carried out with bismuth oxychloride, which was suspended in a little water, and solution effected by the addition of a few drops of hydrochloric acid.

The following procedure is recommended as yielding the best results:

To the somewhat concentrated, but not too strongly acid, solution is added an excess of hypophosphorous acid, and the solution warmed on the water-bath until the supernatant liquid is clear; the solution should then be heated to the boiling-point, and a further addition of the reagent should cause no further coloration. The metal separates as a reddish-gray spongy mass (which is readily filtered and washed); this is collected either upon a weighed filter-paper, or in a Gooch crucible, washed first with boiling-water, and then with absolute alcohol, and dried at 105°.

The filtrate should be tested for bismuth with hydrosulphuric acid, when a slight brown coloration will be obtained if the solution has not been warmed sufficiently long.

The method, it is claimed, serves also for the separation of bismuth from such metals as lime and cadmium, which are not precipitated by hypophosphorous acid.

H. C. L. B.

The Separation of Vanadium from Arsenic. C. Field and E. F. Smith. (*Jour. Amer. Chem. Soc.*, 1896, xviii., 1051, 1052.)—The method is based on the difference in volatility of the sulphides of vanadium and arsenic, when heated in an atmosphere of hydrochloric acid gas, the latter being completely expelled at a temperature little above 150° C., whilst the brown vanadium sulphide is not altered. In the experiments the results of which are given below both sulphides were in perfectly dry condition, and the temperature was not allowed to exceed 250° C.:

Taken.		Left.
Vanadium Sulphide. Gramme.	Arsenic Sulphide. Gramme.	Vanadium Sulphide. Gramme.
0·1303	0·1302	0·1297
0·1290	0·2242	0·1297
0·0828	0·0582	0·0827
0·1306	0·2028	0·1308
0·1403	0·2409	0·1404

The following course was adopted in the analysis of a specimen of vanadinite: 0·2500 gramme of the air-dried and finely-divided mineral was placed in a porcelain boat, which was gently heated in a combustion-tube in a current of dry hydrochloric-acid gas. This treatment expelled vanadic and arsenic oxides, leaving lead phosphate and chloride. The receiver containing the vanadium and arsenic was made alkaline and digested with ammonium sulphide, and from the solution of the sulpho-salts the sulphides were set free by a dilute acid. After washing and drying, the sulphides were separated in the manner indicated above, then converted into oxides, and determined in the usual way. The sum of the constituents determined as lead oxide, phosphoric oxide, vanadic and arsenic oxides, with some lead chloride, amounted to 0·2501 gramme.

C. A. M.

The Separation of Manganese from Copper and Zinc, and of Copper from Zinc and Nickel, etc. P. Jannasch. (*Zeit. f. anorg. Chem.*, xii., 2, 134-142.)—1. Separation of manganese from zinc.—Dissolve about 0·4 gramme of the substance under examination in 10-15 c.c. of water slightly acidulated with hydrochloric acid. Add 15 c.c. of glacial acetic acid, and pour drop by drop, with constant stirring, into a mixture of 40-50 c.c. concentrated ammonia and 30-40 c.c. hydrogen peroxide (3 per cent.). Cover and heat on a water-bath for fifteen minutes. Filter off the precipitate, wash with concentrated and then with dilute ammonia, and finally with warm water. It is then absolutely free from zinc, which latter may be estimated in the filtrate.

2. Manganese from copper.—Proceed precisely as in 1, using, however, a mixture of 60 c.c. ammonia and 50 to 60 c.c. hydrogen peroxide. Heat for half an hour, filter off and wash several times by filling up the filter with a warm solution (30 per cent.) of ammonium acetate in strong ammonia. Then wash with ammonia alone, and finally with hot water.

The copper is estimated in the filtrate by any of the usual methods, or, if preferred, it may be removed from the solution first either (1) by hydrogen sulphide, or (2) by potassium or ammonium sulphocyanide. In the first case the author advocates the use of sulphuric acid, as above, instead of hydrochloric. After filtering off the copper sulphide evaporate the filtrate to get rid of SH_2, and then pour into a mixture of 30 c.c. strong ammonia, and 30 c.c. hydrogen peroxide, and treat as already described. If the copper is precipitated as sulphocyanide, destroy the excess of the precipitate in the filtrate in the usual manner with hydrochloric and nitric acids, and determine the manganese as already described.

The hydrogen peroxide method has yielded excellent results in the author's hands, and its advantages, as compared with methods in common use, are discussed at some length. C. H. C.

The Valuation of Borax. J. G. Heid. (*Zeit. angew. Chem.*, 1896, 679.)—The usual commercial method is to separately determine the various impurities and deduct the sum of these from 100, the difference being taken as the amount of crystallized sodium diborate ($Na_2B_4O_7 + 10H_2O$). Since the amount of various impurities is frequently very great, the analysis often requires a long time, and in consequence the author has devised the following method:

Ten grammes of the borax are dissolved in 250 c.c., and the sodium chloride estimated gravimetrically in an aliquot portion of the solution. A second portion (25 c.c.) is diluted with water in a flask, and boiled with an excess of hydrochloric acid for five minutes. The liquid is then evaporated to dryness on the water-bath, and the sodium chloride in the residue determined. From the result that previously found is deducted, and the difference calculated into the equivalent of sodium diborate. C. A. M.

The Use of Boric Acid in the Analysis of Silicates. P. Jannasch. (*Zeit. f. anorg. Chem.*, xii., 3, 208-218.)—The process consists in fusing the mineral with finely powdered boric acid, and subsequently removing the latter by repeated evapora-

tion with methyl chloride. The pure boric acid, free from alkalis, is prepared by recrystallizing the commercial salt, first from 2 to 3 per cent. hydrochloric acid, and then from water. It is dried, fused, and powdered, as previously described (ANALYST, xx. 51).

The methyl chloride must be freshly prepared, as it seems to lose its efficiency after long keeping. For this purpose the author employs a wash-bottle with ground-in tubes, instead of the usual cork, into which he pours 250 c.c. of pure anhydrous methyl alcohol. A rapid current of hydrochloric acid gas is then passed through the cooled liquid for two or three hours.

The analysis is conducted as follows:

Mix in a crucible of 60-65 c.c. capacity 1 gramme of the powdered silicate with from three to eight times the quantity of boric acid, the proportion depending on the ease with which the substance is decomposed. Heat gently for five to ten minutes, then strongly, destroying any large bubbles that may be formed with a short platinum wire. When the formation of bubbles has almost stopped, cover the crucible, and continue heating, finally using a blowpipe flame. Place the hot crucible on a pipe-clay triangle immersed in cold water, weighting the lid as a further security against loss. Remove the contents, as far as possible, to a large platinum dish, soak in water, add hydrochloric acid, and evaporate to dryness. Now add about 60 c.c. of methyl chloride, wash down the sides of the dish with the same liquid, and evaporate at a temperature of about 75-80°. Repeat with fresh quantities of methyl chloride three or four times. Wash down the *outside* of the dish (which may have a slight incrustation of boric acid) with methyl chloride into a large clock-glass, and evaporate to dryness—no residue should be left.

The complete removal of the boric acid from the contents of the dish may be ascertained by placing a Bunsen burner near the water-bath, and fanning a little of the vapour towards the flame, which will exhibit the characteristic green colour if any boron compound is still being evolved. A clock-glass should be at hand to place over the dish should the vapour catch fire.

After the final evaporation with methyl chloride, heat the dish for an hour to 110° C., then add 5 c.c. of hydrochloric acid, and proceed in the usual manner.

The method previously described, although of almost universal application for the analysis of silicates is not applicable to the analysis of minerals of the Andalusite group. In the analysis of one of them ("cyanite") the author found treatment with calcium fluoride and hydrogen potassium sulphate, etc., quite unavailing; but, after various experiments, succeeded in effecting complete decomposition by the following means: The powdered material was put in a crucible with 10 c.c. of strong ammonia, diluted with water, and strongly acidulated with hydrofluoric acid, evaporated, fused for some time, the excess of ammonium fluoride being driven off. The silico-fluoride thus produced was treated with dilute sulphuric acid and evaporated, and the excess of acid driven off. The residue was then found to entirely dissolve in dilute hydrochloric acid.

The rest of the paper is occupied with the composition of the mineral in question.

C. H. C.

The Iodometric Determination of Selenious and Selenic Acids. J. F. Norris and H. Fay. (*Amer. Chem. Journ.*, 1893, xviii., 703-706).—It is claimed that the method here described requires fewer reagents, occupies less time, and gives more accurate results than that of Gooch and Peirce (*Am. J. Sci.*, i. [4] 31), hitherto considered the most suitable volumetric process. It depends on the reaction between sodium thiosulphate and selenious acid in the presence of hydrochloric acid, in which, although the complete reaction is not known, one molecule of selenious acid is exactly equivalent to four molecules of sodium thiosulphate.

Determination of Selenious Acid.—The selenious acid used in the test experiments was prepared by evaporating commercial selenium to dryness with concentrated nitric acid, reducing the dioxide thus obtained by sodium sulphite and hydrochloric acid, again oxidizing the selenium with nitric acid and subliming the residue. About two grammes of the selenious acid were dissolved in water and made up to 500 c.c., aliquot portions being taken for each determination.

The definite portion taken was diluted with ice-water and 10 c.c. of hydrochloric acid (1·12 sp. gr.), an excess of decinormal thiosulphate solution added and titrated back with standard iodine solution. The titration was not affected by a large excess of hydrochloric acid when the solution was cold. Results:

SeO_2 taken. gramme.	SeO_2 found. gramme.	SeO_2 taken. gramme.	SeO_2 found. gramme.
0·0829	0·0829	0·1366	0·1367
0·1242	0·1242	0·1656	0·1659
0·1242	0·1242	0·2070	0·2071

Determination of Selenic Acid.—The selenic acid was prepared by dissolving about two grammes of selenium dioxide in 200 c.c. of water, and adding a strong solution of potassium permanganate until a pink colour remained after heating for thirty minutes at 60° C. Sulphurous acid was then added until only a small amount of manganese dioxide remained, and the solution filtered and diluted to 500 c.c.

In making a determination 25 c.c. of concentrated hydrochloric acid were added to a definite portion of this solution, which was then diluted to 100 c.c. After being boiled for an hour, care being taken not to allow the volume to go below 75 c.c., the liquid was cooled, diluted with ice-water, and the selenious acid determined by titration. Results:

SeO_3 taken. gramme.	SeO_3 found. gramme.	SeO_3 taken. gramme.	SeO_3 found. gramme.
0·1011	0·1009	0·1598	0·1595
0·1067	0·1067	0·2023	0·2024
0·1067	0·1065	0·2665	0·2662

Determination of a mixture of Selenious and Selenic Acids.—Two portions of a solution containing known quantities of selenious and selenic acid were measured off. In one the selenious acid was determined by direct titration; in the other the total selenium, after reduction of the selenic acid. Some selenium was precipitated on heating the solution during the reduction, but this dissolved when the chlorine was evolved. Results:

SeO_2 taken. gramme.	SeO_2 found. gramme.	SeO_2 taken. gramme.	SeO_2 found. gramme.
0·0467	0·0467	0·1013	0·1015
0·0467	0·0466	0·1013	0·1016
0·1868	0·1865	0·1012	0·1015

The reagents used in the test experiments were all carefully purified. Resublimed iodine was sublimed from one-third its weight of potassium iodide, and dissolved in potassium iodide free from iodate. The sodium thiosulphate was purified by recrystallization, and the solution standardized with resublimed iodine and pure sodium arsenite. C. A. M.

Alcohol as a Source of Error in Volumetric Analysis. L. F. Kebler. (*Amer. Jour. Pharm.*, 1896, lxviii., 667-673.)—Referring to Caspari's paper (ANALYST, xxi., 293), the author describes experiments which prove the correctness of the conclusions there stated as to the disturbing influence of commercial alcohol in volumetric analysis, but it is further shown that absolutely pure alcohol does not so interfere, except in the case of methyl orange and tropæölin 00. Absolute alcohol was prepared by repeated fractional distillation from commercial alcohol which had been made faintly alkaline with potassium hydrate, and with the purified product thus obtained, the results on titrating alkaloids and alkaloidal residues in alcoholic solution were as accurate as those found in aqueous solution. C. A. M.

APPARATUS.

A New Baryta Tube. H. C. Geelmuyden. (*Zeit. anal. Chem.*, 1896, xxxv., 516, 517.)—In estimating the amount of carbon dioxide in the air by Pettenkofer's method of drawing a known volume of the latter through a tube containing standard baryta water, and titrating an aliquot portion of this with acid after the absorption, it may easily happen that the baryta water changes in volume during the experiment, especially when this is long continued. As a remedy for this, the author has constructed a tube on the principle of the Gay-Lussac burette, which during the absorption is placed almost horizontally, with the open ends of the tubes bent upwards. The wide tube is graduated, and the volume of baryta water is read before and after the absorption, the tube being placed in a vertical position during the readings. C. A. M.

LEGAL.

PROCEEDINGS IN THE COURT OF APPEAL.

MILK OF SULPHUR PROSECUTION.

(*Reprinted from the "Pharmaceutical Journal" of February* 6, 1897.)

The case of Sandys v. Simpson came before Mr. Justice Wright and Mr. Justice Bruce in the Divisional Court, on Monday last, upon a case stated by the Justices of Heanor in the county of Derby. It appeared that at the Petty Sessions held at Heanor on October 26 last,

an information was preferred by Henry Stair Sandys against a chemist and druggist named David Osborne Simpson, for that he (the respondent), did on August 18, 1896, at Heanor, sell to one Joseph Hewitt, to his prejudice, a certain drug, namely, "precipitated sulphur," which was not of the nature, substance and quality of the article demanded by the purchaser, in that it contained 46 per cent. of sulphate of lime. The appellant, Mr. H. S. Sandys, is an inspector of Weights and Measures for the county of Derby, charged with the execution of the Sale of Food and Drugs Act, 1875, under Section 6 of which the information was laid. When the matter was before the Justices, on the charge being read over to the respondent, he did not plead guilty or not guilty, but before any evidence was given, admitted selling the article complained of, namely, milk of sulphur, and stated that when he was weighing it he informed Joseph Hewitt that he had two preparations of the article, viz., "milk of sulphur" and "precipitated sulphur." The respondent offered to change the article, and to supply Hewitt with precipitated sulphur, which he designated as "the pure," but Hewitt insisted on being supplied with the article that the respondent was in the act of weighing, viz., milk of sulphur, and he was accordingly served with milk of sulphur. The respondent further stated that milk of sulphur was a preparation he had sold for forty or fifty years, and that it was what his customers usually expected to be supplied with. He also stated that it was his custom to keep pure precipitated sulphur for medicinal purposes, but that he was seldom asked for it and his customers had repeatedly returned it to him when supplied to them, and asked that they might instead be supplied with milk of sulphur, which was the article he (the respondent) at first thought Hewitt required. The respondent further made the following statement: "I rather sealed my own doom in that I used a printed precipitated sulphur label without writing on it 'milk of sulphur,' but I had used up all the 'milk of sulphur' labels a few weeks ago, and being in a hurry and not very well that day I put this 'precipitated sulphur' label on in mistake." It was proved that Hewitt was the County Inspector and was at Heanor on August 18, 1896. Hewitt, acting on the appellant's directions, that day went to the respondent's shop and asked for half a pound of precipitated sulphur. Hewitt duly notified to the respondent his intention to have the article analysed by the public analyst, and offered to divide it into three parts in accordance with Section 14 of the Statute, and duly divided it into three parts, delivering one part to the respondent. The requirements of the Statute were complied with, and upon one of the parts being analysed by the Public Analyst it was found to contain 46 per cent. of sulphate of lime. The appellant alleged that the article supplied and sold by the respondent to Hewitt was not of the nature, substance, and quality of the article demanded by Hewitt, who on cross-examination denied the allegation that the respondent had offered whilst weighing the milk of sulphur, or at any other time, to supply precipitated sulphur, or to change it. The respondent was not sworn, nor was any evidence called on his behalf. The information was heard before four justices of the peace, and was dismissed on the decision of the majority. The grounds of the majority for dismissing the information were that the respondent was well known to them as a most respectable and honest tradesman, and they fully believed his statement, notwithstanding the evidence given by Hewitt.

Mr. Hextall appeared in support of the appeal.

The respondent was not represented.

Mr. Justice Wright said he should think very likely the Justices were wrong in this case, but they had a right to go wrong if they could reconcile it with their consciences. At any rate that Court could not set them right.

Mr. Justice Bruce concurred.

Appeal dismissed without costs.

THE ANALYST.

APRIL, 1897.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

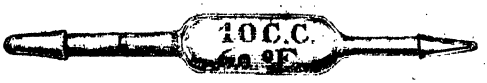
THE monthly meeting of the Society was held on Wednesday evening, March 3, at the Chemical Society's Rooms, Burlington House, the President (Dr. Bernard Dyer) being in the chair.

The minutes of the previous meeting were read and confirmed.

The following gentlemen were proposed for election—as members: Leonard de Koningh, F.I.C., Analytical Chemist, 325, Kennington Road, S.E.; Alexander Henry Mitchell Muter, A.I.C., Analytical Chemist, 325, Kennington Road, S.E.; William Crowder, F.I.C., Analytical and Consulting Chemist, 271, Evering Road, Upper Clapton, N.E.; Alexander Edwin Tucker, F.I.C., Analytical Chemist, 35, Paradise Street, Birmingham; John Heron, F.I.C., Analytical and Consulting Chemist, 110, Fenchurch Street, London. E.C. As associate: Richard Murray, assistant to Mr. Benjamin Watmough, Wakefield.

The following papers were read: "The Composition of Milk and Milk Products," by H. Droop Richmond; "The Detection of Mixtures of Diluted, Condensed, or Sterilized Milk with Fresh Milk," by H. Droop Richmond and L. K. Boseley; "The Estimation of Milk-sugar in Milk," by H. Droop Richmond and L. K. Boseley; "The Constitution of Milk," by H. Droop Richmond; "Copper in Preserved Vegetables," by R. Bodmer and C. G. Moor, M.A.; "Coffee Palace Coffee Infusions," by E. G. Clayton.

The following gentlemen were elected—as members: Hugh Candy, B.A., B.Sc., Lecturer on Chemistry at the London Hospital; Frederick William Harris, Public Analyst for Burnley (Lancashire); John H. B. Jenkins, Chemist to the Great Eastern Railway Company; Henry de Mosenthal, F.I.C., Chemist to Nobel's Explosives Company, Limited. As associate: Edward Halliwell, assistant to Mr. Fairley.



A SPECIFIC GRAVITY PIPETTE.

By W. F. KEATING STOCK, F.I.C.

(Read at the Meeting, January 13, 1897.)

I HAVE lately found the little instrument described below of great use in cases where the gravity of small samples of castor-oil, glycerin, and other matters of high viscosity was required. It consists of a 10 c.c. pipette, with the bulb occupying a central position on the stem. The bulb is of the usual elongated form, but instead of being

cylindrical, it has a flat side, which gives it a stable seat on the pan of a balance. It is six inches in length, and each end of the stem is closed by a ground glass cap, having a good long hold on the stem. The graduation mark is placed one inch below the upper orifice of the stem, and the cap on the lower end is ground so as to fit within 1 m.m. of the point. The point is of such a bore that glycerin passes freely at ordinary temperatures under slight pressure. To use the pipette a piece of suitable size indiarubber tubing is slipped over the open upper end, the liquid to be tested is brought to the required temperature, and the pipette is filled through the pointed end by sucking at the indiarubber tube; when the liquid has risen just above the mark the point is closed by a finger, the indiarubber tube is removed, and the first finger of the right hand is placed over the orifice, the pipette being then held, as usual, between the thumb and second finger. The lower part of the stem is then freed from liquid by wiping with soft filter paper. The liquid is adjusted to the mark and the lower cap is put on. A little roll of filter paper is now used to remove any liquid adhering to the inner walls of the tube above the graduation mark, the upper cap is put in place, and the whole instrument is then wiped clean with a soft cloth, and is ready for weighing. It is not my wish to compare it with any other form of specific gravity apparatus. I have found it easy to use, easy to clean, and accurate. My own instrument was made by cutting down a 10 c.c. pipette and fitting it with caps, etc., in the laboratory. Messrs. Brady and Martin, of Northumberland Road, Newcastle on-Tyne, have asked to be allowed to reproduce it in convenient sizes (probably 5, 10 and 25 c.c.), and they will probably have the pipette for sale shortly, under the name of "Stock's Specific Gravity Pipette."

Discussion.

Mr. Richmond desired to know how Mr. Stock ascertained that the liquid was of the proper temperature within the instrument.

Mr. Stock said he had not determined the difference between glycerin at 15·5° C. in a small beaker and the temperature of the liquid in the pipette when it had taken a few seconds to fill; he did not imagine that the difference would be very great.

NOTE ON THE PRESENCE OF COPPER IN OYSTERS.

By W. F. Lowe, A.R.S.M., F.I.C.

(Read at the Meeting, December 2, 1896.)

A short time ago a few oysters were brought to me by a friend, who said he had reason to believe that they contained copper, as he had examined one or two and found copper in them.

On examination I found this to be the case. In some of the oysters the presence of copper was apparent to the eye, as they were of a bluish-green colour, not all over, but in patches; and in one oyster the whole of the colour seemed to be concentrated in the large muscle used by the animal in opening and closing its shell.

In some of them, however, which also contained a considerable quantity of copper, no bluish colour could be seen, the only difference being that the dark portions of the fish had a somewhat olive-green tint that would not be observed unless they were closely examined.

The shells were free from colour, and no copper was found in them.

The quantity of copper in a single oyster amounted to 40 milligrammes, or about $\frac{6}{10}$ grain, so that but few of them were required to produce very unpleasant results.

They were obtained from the Mumbles, near Swansea, and had probably been laid down in the neighbourhood of some refuse from the copper works.

DISCUSSION.

The PRESIDENT (Dr. Stevenson) remarked that it was easy, during the operation of incineration over a Bunsen flame, to introduce traces of copper from the burner, so that in cases of this kind it was undesirable to use brass burners.

Mr. BODMER said that certain French oysters of a green colour contained less copper than some others whose colour was much less pronounced, so that the colour did not appear to be due to copper at all. It was a well-known fact, however, that oysters did, as a rule, contain copper. In a recent case in which he had been engaged, connected with peas containing copper, it had been brought forward for the defence that a dozen oysters contained rather more than a grain of copper—a quantity somewhat in excess of that contained by 1 lb. of the peas in question.

Mr. HARVEY said that, in his experience, copper was very widely disseminated in shell-fish; but he did not regard the green colour constantly observed in them as having any necessary connection with the presence of copper. He instanced the case of an arrangement of tanks for hatching salmon ova, in which the water was suspected of having dissolved copper from the taps, which, however, was found not to be the fact. However, he had always connected the delicate pink colour of the ova of salmon with the presence of a very minute quantity of copper.

The PRESIDENT said that the oyster was not singular in containing copper. The human body, for instance, nearly always contained small quantities, especially the liver. It might not necessarily be a natural constituent, but was probably derived from certain articles of food, or from cooking utensils.

THE STATEMENT OF ANALYTICAL RESULTS.

BY J. F. LIVERSEEGE, F.I.C.

(*Read at the Meeting, December* 2, 1896.)

THE question I wish to discuss is, not how far should analytical results be given in reports, but to ask what are the principles by which the number of significant figures given in a result should be decided.

The following analytical results have been reported in recent prosecutions under the Sale of Food and Drugs Act:—

I. A whisky was 34·71° under proof.

II. Alcohol, 78·03 per cent. in spirit of nitrous ether.

III. Peas containing 3·11 grains of sulphate of copper per pound.
IV. Butter with 19·88 per cent. of water present.
V. Milk adulterated with 11·77 per cent. of added water.
VI. Coffee adulterated with 68 per cent. of chicory.

The first four are statements of fact, the others are expressions of opinion. If two distillations of alcohol often differ by 0·2 per cent., what is the use of giving a second decimal place? Is there any probability that the analysts of III. and IV. would again obtain 3·11 grains or 19·88 per cent. as the result of other analyses? Ought a milk standard to be used to calculate the added water to 1 per 10,000? If these second decimal places have no meaning, is it wise to appear to claim such a high degree of accuracy? It seems to me to be reasonable to expect that a *second* decimal place should not appear on a certificate, unless it is probable that the *first* could be again obtained in another analysis, and that, unless the unit is certain, adulteration should only be certified to 5 or 10 per cent.: in VI., for instance, report 65 or 70 per cent. of chicory to be present. Suppose that in I. another analyst found 34·91° under proof, some magistrates would consider this a much more serious difference than if one analyst certified 34·7° and another 34·9° under proof. I also think that in V. the analyst would have felt rather foolish if, in answer to questions, he had admitted that there might be 15 or 20 per cent. of water added, instead of the 11·77 per cent. certified to be present.

In water analysis decimals appear very largely; the following are single analyses (not averages) taken from standard works. Total solid matter, 108·88, 220·92, 320·72; nitrogen as nitrates, 6·499, 14·717, 19·858; ammonia, 1·366; organic nitrogen, ·141, ·298, ·531; organic carbon, ·142, 1·792, 2·662; total hardness, 116·9, 140·8.

It appears to me that in each case the last figure of the result is superfluous and should be omitted, the previous figure being increased by one if the last figure is 5 or more. If 250 c.c. of water were taken for the total solid matter recorded as 220·92, the residue would weigh 0·5523 gramme, and each milligramme error would affect the result by 0·4; one decimal place is therefore as much as should be put in any ordinary analysis. In the determination of ammonia, an error of 0·5 in 5 c.c. of ammonium chloride solution is possible, or 10 per cent. I would suggest that to proceed by units from 1 to 25, and then by 5 up to 100, irrespectively of the decimal place, would be better than putting meaningless figures; 1·366 would then become 1·4. When the amount of hardness present exceeds 50, the unit figure becomes very uncertain, and 116·9 may for practical purposes be written 117 or 120. Similarly, nitrogen as nitrates, "6·499," should be written 6·5; and my experience of organic carbon and nitrogen makes me think that the third decimal place cannot be depended on. It is no doubt advisable to record the exact figures found in the laboratory notes, but in reports and printed matter these extra figures appear to me to be unadvisable and misleading.

These superfluous decimals also appear in other chemical work. A recent paper on lemon-juice stated that one fluid ounce contained 34·089 grains of citric acid; the milk analyses giving such specific gravities as "1·03148" are well known, and the following quotations cannot easily be surpassed. "Use a 0·0845691 per cent. solution of K4FeCy6, 3Aq." "The factors for a volumetric solution of iodine are:—Salicylic acid, 0·18132606; thymol, 0·2956772; and β-naphthol, 0·37843106."

In text-books, the meaning of "per cent." is sometimes doubtful; it may be by weight, or by volume, or grammes per 100 c.c. In my own notes, I have for some years been in the habit of using "%" in cases where there can be no ambiguity: of adulteration "%," for instance, and for per cent. *by weight*. Per cent. *by volume* has been expressed by the sign "v/v" (*i.e.*, volume on volume), and grammes per 100 c.c. by "w/v" (*i.e.*, weight on volume). These signs show readily exactly what is meant. Alcohol S.G. 0·838, for instance, 84 % = 88·7 v/v = 70·4 w/v.

Discussion.

The President (Dr. Stevenson) said he thought that, as a rule, insignificant decimal places were better dispensed with, but in some cases it was perhaps a matter of convenience to insert them. For instance, in water analyses, where some of the factors really required the use of three decimal places for their proper expression, it was more convenient to state the results all through to three decimal places than to jump about from two to three. In cases where the third place had no real significance it might be filled by a cipher for the sake of symmetry.

Mr. Allen said that he was in the unusual position of disagreeing with the President, for he thought that, if a fraction were cut short by omitting the concluding figure, the place of this figure ought not to be filled by a cipher, inasmuch as a definite value was thereby assigned to it which was not intended. If the figure was assumed to have no significance whatever, the place ought to be left blank.

There was only one excuse for the use of these long decimals, and that was that the chemist gave the results he got. He put them forward, not as the strictly correct results, but as the actual results of his work, and if these results required a decimal fraction to express them, they should be stated accordingly. That was the only excuse, except in the case of gold and steel analyses. The third decimal place in a steel analysis had a distinct significance in the case of phosphorus and sulphur, and affected the second place, where any variation became of consequence. He was afraid the public sometimes looked upon analysts as quacks, more or less, because they reported to two or three places of decimals in cases in which it was exceedingly doubtful if they would get on repetition a result agreeing even to the first place of decimals. The Society itself occasionally offended in this respect, for, in the circulars recently issued to members respecting the form of milk certificates, and which was made necessary by the decision in the case of Fortune *v.* Hanson, the sum of the results of a milk analysis was directed to be stated to two decimal places! He (Mr. Allen) felt very strongly that it was a mistake to pretend to express results with extreme accuracy unless such accuracy could be approached reasonably closely; and he thought that, except in special cases like those he had mentioned, the sooner the practice was discarded the better.

Mr. Cassal thought there was a great deal to be said on both sides of the question. He agreed with a good deal of what Mr. Allen had said, and to a certain extent with the author of the paper, but it had to be remembered that public analysts were not their own masters in all matters of this sort. Mr. Allen had alluded to milk, and had caused some laughter by mentioning the fact that the statement of results to the second decimal place had been suggested in the Society's circular; but what was one

of the effects of the case of Fortune *v.* Hanson? It was this: If public analysts wished to avoid being put to serious inconvenience, and wished to avoid following the practice which in his student days was known as "cooking," the percentage of added water would have to be stated to a decimal place in most cases. If the percentage of added water was stated to the nearest whole number, as used to be done, it would be necessary to alter the percentage of non-fatty solids, which had now to be given on the certificate, for it necessarily happened that in most cases the percentage of added water calculated from the non-fatty solids ran into a decimal. It was not necessary, of course, to go to the second place of decimals.

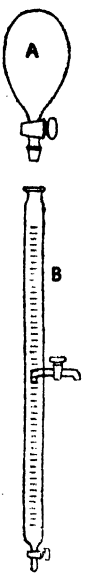
With regard to water analyses, he thought that absolutely unnecessary figures ought not to be stated at all, though in one place he had been for a long time practically compelled, through no fault of his own, to state the result of certain water analyses in parts per 100 million (laughter). It was done originally, he believed, because it was thought that those who had to consider the figures understood whole numbers, but did not quite appreciate decimals, and the result was that they were provided with "parts per 100 million" because they had then got something to catch hold of (laughter).

The real way out of the difficulty was to apply common sense to the matter. It was one which required to be dealt with according to the individual merits of every case in which it arose.

Mr. BEVAN said that the case of Fortune *v.* Hanson had been to a large extent set aside by the decision in the case of Bridge *v.* Howard. In that decision it was clearly shown—at least the judge allowed it to be understood—to be quite unnecessary to state the quantity of added water to a decimal fraction. The percentage of solids-not-fat in the case of Bridge *v.* Howard was 7·95, and the added water, calculated to one decimal place, was 6·5. He (Mr. Bevan) had called it 6 per cent., and the judge, having made the calculation for himself, said that as a matter of fact the percentage of added water had been under-stated, but took no exception to this.

Mr. CASSAL said that his experience was that the accuracy of an analysis would be doubted by non-experts if, when the figures were asked for, the actual figures, including the decimals, were not given. He might say that on one occasion a magistrate wanted him to leave out the decimal figures in the non-fatty solids reported in his certificate in order that the method of calculating the amount of added water might be made "more clear."

The PRESIDENT said that Mr. Cassal's experience appeared to be exceptional. He himself had been in the habit for twenty-five years of stating whole numbers only, without fractions, in the case of milk. In regard to certain other things, such as coffee, he had taken still greater latitude, as he would not venture to distinguish between, say, 55 and 60 per cent. in the case of coffee adulterated with chicory, and he had found magistrates sufficiently reasonable to see the force of this.



He was glad to think that the difference of opinion between Mr. Allen and himself was, after all, but a small one.

A MODIFIED SCHMID PROCESS.

By R. W. Woosnam.

(*Read at the Meeting, January* 13, 1897.)

The difference of a milligramme in the weight of butter-fat obtained by the usual processes from 5 c.c. of milk is often of much greater importance than would be supposed at first sight. Especially is this the case with separated milks, where a variation of 0·02 per cent. (the result of a difference of one milligramme in the weight) may sometimes even constitute the margin between a good and an only moderate separation. In butter-factories, where large quantities of milk are dealt with, this difference often represents a considerable item in pounds of butter.

In order to ensure a more exact result, without at the same time unduly prolonging the process, I have devised the piece of apparatus as shown in the accompanying figure. It is constructed in two parts, as follows:

(A) A boiling-flask, with tap, the mouth ground to fit the top of B.

(B) A graduated 100 c.c. burette, with small tap at the side, placed preferably at about the 50 c.c. mark.

In making a determination, 25 c.c. of the milk are pipetted into the boiling flask A, and about 28 c.c. (roughly) of strong hydrochloric acid added. For this purpose, a 25 c.c. pipette, with stem sufficiently small to pass through the tap, is recommended. The flask is then placed in boiling water, and agitated frequently until the contents assume a *pale* brown colour. This will generally take place in about two minutes, and it is important that the action should not be allowed to proceed too far, or the sugar caramelized will be, to some extent, extracted by the aqueous ether at the next stage. The flask is now cooled thoroughly, and 50 c.c. of ether added. The tap with which the flask is fitted is then closed, and the whole shaken vigorously for some moments, after which it is fixed firmly into the top of the burette B, the ground-surfaces making a tight joint. When the ether layer has separated, the tap is turned on, to allow the liquids to flow gently into the burette. The measurement of the ether layer is next read off, and, after adjusting the levels of the liquids by manipulating the two taps of the burette, an aliquot part of the ether layer is drawn off from the side-tap into a suitable weighed vessel, the ether driven off, and the fat weighed in the usual manner.

The results obtained have been very satisfactory.

The advantages claimed are: That a larger quantity of milk may be worked upon; that the tapped boiling-flask lends itself more perfectly for thoroughly shaking with the ether; that the reading of the ethereal layer is more exact; that, when desired, more than one aliquot part of the fatty ether may be drawn off; and, lastly, that greater accuracy is obtained than by the old methods.

The apparatus is made by Messrs. Müller, of 148, High Holborn.

THE DISTILLATION OF FORMALDEHYDE FROM AQUEOUS SOLUTIONS.

By Norman Leonard, B.Sc., Harry M. Smith, and H. Droop Richmond.

(*Read at the Meeting, February* 3, 1897.)

In a paper (Analyst, xxii., 5) two of us (L. and S.) have given the results of distillation of aqueous solutions of formaldehyde, expressed as grammes of formaldehyde distilled in given fractions. In the Analyst (xx., 193) one of us (R.) has shown that when dilute solutions of the fatty acids of the acetic series are distilled, the quantity of acid found in the distillate is expressed by the formula

$$100 - y = \frac{(100 - x)^a}{100^{a-1}},$$

provided that condensation in the retort does not take place.

y = percentage of total acid in distillate.

x = volume of distillate expressed as percentage.

It was further shown that a is the rate of distillation—*i.e.*, the ratio of the percentage of acid in the vapour (*i.e.*, parts of acid per 100 of vapour) to the percentage of acid in the solution in the retort (*i.e.*, parts of acid per 100 of solution).

We have examined the results yielded by the distillation of formaldehyde, and find that the quantity of formaldehyde distilled is expressed by the formula

$$100 - y = \frac{(100 - x)^{1\cdot65}}{100^{0\cdot65}}.$$

The annexed table gives the results found compared with those calculated by the formula; it is seen that the agreement is very close:

Vol. of Fraction Distilled.	Formaldehyde in Fraction.							
	Found	Calc.	Found	Calc.	Found	Calc.	Found	Calc.
0 – 20	·0024	·00240	·0023	·00234	·0026	·00237	·199	·208
20 – 40	·0021	·00204	·0018	·00199	·0020	·00201	·180	·177
40 – 60	·0017	·00164	·0017	·00160			·139	·142
60 – 80	·0011	·00117	·0012	·00114	·0031	·00334	·105	·1015
80 – 100	·0005	·00055	·0006	·00053			·053	·0475
Total ...	·0078	·00780	·0076	·00760	·0077	·00770	·676	·676

We may again point out that the volatility of a substance in dilute aqueous solution is entirely independent of the properties of the substance in a pure state, and is solely dependent on its solubility in water. The following table of rates of distillation and properties will show this:

Name.	Rate of Distillation.	Properties in Pure State.
Formaldehyde ...	1·65 ...	Gas, b.-p.,—21°
Formic acid ...	·4 ...	Liquid, ,, 100°
Acetic acid ...	·667 ...	,, ,, 118°
Propionic acid ...	1·111 ...	,, ,, 137°
Butyric acid ...	2·0 ...	,, ,, 162·5°

THE COMPOSITION OF MILK AND MILK PRODUCTS.

By H. Droop Richmond.

(*Read at the Meeting, March* 3, 1897.)

Of the 32,362 samples examined in the laboratory of the Aylesbury Dairy Company during 1896, 26,723 consisted of milk.

The average composition of 11,633 samples taken from the railway churns on arrival at the depôts of the company is given in Table I.

Table I.—Average Composition of Milk Inwards.

Month.	Morning Milk.				Evening Milk.

Average ...	1·0325	12·60	3·63	8·97	1·0321	12·95	3·99	8·96	1·0323	12·78	3·81	8 97

The fat in all these samples has been estimated by a centrifugal process of the Leffmann-Beam type, various centrifugal machines having been used; the solids-not-fat and total solids have been in the bulk of the analyses calculated by the formula given in a previous report (Analyst, xix. 65, cf. also xx. 57). In 100 test experiments the difference between the results calculated and those found has not exceeded 0·15 per cent.

The following analyses are of abnormal milks:

	I.	II.
Specific gravity	1·0292	1·0303
Total solids	11·57	12·42
Fat	3·51	4·00
Milk-sugar	3·41	3·71
Proteids	3·84	3·89
Ash	0·81	0·82
Solids-not-fat	8·06	8·42

A further sample (not authenticated) was received from the same source as No. I., and was sour when analysed. The results were:

Total solids	11·17	
Fat	3·65	
Proteids	3·36	containing nitrogen ·528
Ash	0·71	
Solids-not-fat	7·52	

I would draw attention to the fact that the best method of analysing sour milks is to estimate fat by Werner-Schmid method, total nitrogen by Kjeldahl method, and ash; these three data, taking 3·0, ·50, and ·70 as limits respectively, are, in my opinion, sufficient to show whether the sample be genuine or adulterated. No reliance can be placed on an estimation of the solids-not-fat in a sour milk, because it is in itself unreliable; differences of over 1 per cent. were found in the total solids of a sour milk, between estimations in one case drying till the loss was less than 1 milligramme in one hour, and in the other till the loss was less than 3 milligrammes in three hours.

It has long been known that milk received on Mondays is poorer than that received on other days of the week. The following table gives the average percentage of fat found on each day of the week; it is deduced from a series of 5,414 analyses, and is chosen, not because it represents the average composition of milk, but because the results are comparable from day to day.

Day.	Percentage of Fat.
Sunday	3·74
Monday	3·70
Tuesday	3·78
Wednesday	3·75
Thursday	3·75
Friday	3·75
Saturday	3·73
Average of week ...	3·74

The average composition of clotted cream was:

	Maximum.	Minimum.	Average.
Total solids	75·18	56·42	67·64
Fat	68·23	46·66	59·16
Ash	0·90	0·52	0·68
Solids-not-fat	11·31	6·40	8·48

The following percentages of water in butter have been found during the year:

Description.	Maximum.	Minimum.	Average.
English fresh butter ...	15·18	12·40	13·82
,, salt ,, ...	17·92	10·46	13·94
French fresh ,, ...	15·94	11·76	14·40
,, salt ,, ...	14·35	9·35	12·21

The samples of English butter were all examined shortly after churning; it is seen that there is practically the same percentage of water in fresh and salt butter. The sample containing 17·92 per cent. of water was a very small quantity, churned for a special purpose, and was not worked to the same extent as usual. Two other samples of salt butter contained just 16 per cent. of water, and the evidence obtained this year goes to show that the limit of 16 per cent. which has been proposed for water in butter is a reasonable one.

A series of determinations of the refractive index of butters prepared in the laboratory was carried out. The following readings were obtained with Zeiss' butyro-refractometer at 35° C.:

Maximum.	Minimum.	Average.
48·5	45·2	46·5

In connection with this, it is interesting to record a few other figures:

THE DETECTION OF MIXTURES OF DILUTED CONDENSED OR STERILIZED MILK WITH FRESH MILK.

By H. Droop Richmond and L. K. Boseley.

(*Read at the Meeting, March* 3, 1897.)

There are three methods which may be employed for the detection of mixtures of diluted condensed or sterilized milk with fresh milk.

The first of these, which was pointed out by Faber (Analyst, xiv. 141), depends upon the state in which the albumin exists. It is probable that it is in combination with a base, as on heating milk no coagulation of albumin takes place, but on acidifying, or saturating with magnesium sulphate, the albumin separates with the casein. The albumin appears to be changed from a soluble to a colloidal form.

Secondly, as we have before pointed out (Analyst, xviii. 174), if milk has been heated for some length of time, the rotary power of the milk-sugar undergoes a serious reduction, the cupric reducing power not changing to any appreciable extent.

Thirdly, we propose to describe a method that may be of some use in conjunction with the foregoing. It is based upon the fact that the cream rises with extreme slowness—in three hours practically no cream is observed on the surface of sterilized or diluted condensed milk, and in six hours the layer is only about one-tenth of that given by new milk. If sterilized milk be allowed to stand for twenty-four hours, or more, the bulk of the cream will rise to the surface, but the quantity will be less than that yielded by new milk. The cream will, however, contain a distinctly larger percentage of fat, about 40 per cent., as against less than 30 per cent. in the cream yielded by new milk.

The following figures will illustrate this fact:

Sterilized Milk Allowed to Stand for Six Hours.

	No.	Per cent. of Fat in Milk.	Per cent. Cream Risen.	Per cent. Cream for 1 per cent. Fat.	Per cent. Fat in Cream.	Per cent. Fat in Skim Milk.

Diluted condensed.	6.	3·62	0·3	·08	—	—

* With sodium light.

STERILIZED MILK ALLOWED TO STAND FOR TWENTY-FOUR HOURS.

No.	Per cent. Fat in Milk.	Per cent. Cream.	Per cent. Fat in Cream.	Per cent. Fat in Skim Milk.
1.	4·30	7·0	46·8	1·10
2.	3·80	6·0	41·8	1·37
3.	4·25	8·8	39·0	·90
4.	4·10	8·7	41·0	·58
5.	5·35	11·1	41·4	·85
6.	3·62	0·8	—	3·48

NEW MILK ALLOWED TO STAND FOR SIX HOURS.

No.	Per cent. of Fat in Milk.	Per cent. Cream.	Per cent. Cream for 1 per cent. Fat.	Per cent. Fat in Cream.	Per cent. Fat in Skim Milk.
1.	4·05	9·2	2·27	17·4	2·70
2.	4·20	11·2	2·66	16·5	2·65
3.	3·90	9·8	2·51	15·9	2·60
4.	3·70	9·8	2·69	18·0	2·15
5.	4·45	13·5	3·03	16·8	2·30

The samples numbered from 1 to 5 were yielded by the same cows in each case.

Condensed unsweetened milk, which has been diluted to the original volume with water, has all the analytical characteristics of sterilized milk, and there appears to be at present no method of distinguishing between them.

To distinguish new milk, on the one hand, from milk which has been sterilized on the other, the following methods may be employed :

(i.) Place 100 c.c. of milk in a graduated cylinder, and allow it to stand for six hours at 60° F. (15·5° C.) ; note the percentage of cream. If less than 2·5 per cent. of cream for each 1 per cent. of fat in the milk has risen to the surface, the milk may be considered suspicious ; if the quantity of cream falls markedly below 2 per cent. for each 1 per cent. of fat, it is highly probable that sterilized milk is present.

(ii.) Estimate the albumin by the method of Hoppe-Seyler, or, better, those of Sebelein or Duclaux. If less than ·35 per cent. is found, sterilized milk may be considered to be present.

(iii.) Estimate the milk-sugar by the polariscope, and also gravimetrically in duplicate ; if the difference between the two estimations be more than ·2 per cent., it will be corroborative evidence of the presence of sterilized milk. It is doubtful whether a proportion of sterilized milk much below 30 per cent. could be detected when mixed with new milk.

The proportion of sterilized milk may be deduced from the percentage of soluble albumin by the following formula :

$$\text{Percentage of sterilized milk} = \frac{0{\cdot}4 - \text{Percentage of soluble albumin}}{0{\cdot}4} \times 100.$$

This is based on the supposition that new milk contains 1·4 per cent. of albumin, while in sterilized milk the albumin is removed.

The following is the formula for deducing the percentage of sterilized milk from the cream rising test :

$$\text{Percentage of sterilized milk} = \frac{2{\cdot}5 - \frac{C}{F}}{2{\cdot}2}.$$

The estimation of albumin is the most reliable test. There are many causes which influence the rising of cream, such as the temperature to which the milk has been warmed or cooled, the size of the fat globules, which varies with the stage of lactation, and the acidity of the milk, and quantitative deductions may be occasionally misleading.

It must be remembered, however, that no sharp distinction can be drawn between milk which has been raised to a temperature over 70° C. for a short period, and which naturally is not sterilized in the true sense of the term, and milk which has been heated for a sufficient length of time to destroy all microbial life. For this reason a milk should not be reported as sterilized solely on the result of a very low percentage of albumin if neither the "creamometer" nor the milk-sugar tests give corroborative indications. It is probable that the milk in this case has been merely scalded.

The following figures by C. H. Stewart (*Brit. Med. Journ.*, 1896, 626) show the percentage of albumin found in milk raised to various temperatures:

Time of Heating.	Soluble Albumin in Fresh Milk.	Soluble Albumin in Heated Milk.
10 min. at 60° C.	·423	·418
30 ,, ,,	·435	·427
10 65° C.	·395	·362
30 ,,	·395	·333
10 70° C.	·422	·269
30 ,,	·421	·253
10 75° C.	·380	·07
30 ,,	·38	·05
10 80° C.	·375	none
30 ,,	·375	none

The following analyses will show to what extent the method can be depended upon:

							Percentage Sterilized.		
No.	Fat.	Per cent. Cream.	Cream Fat.	Albumin.	Milk-Sugar.	Milk-Sugar Pol.	Actual.	Cal. Cream.	Cal. Albumin.
1.	3·86	7·2	1·87	·30	4·85	4·65	33	29	25
2.	4·10	9·6	2·34	·34	4·79	4·68		Genuine	
3.	3·90	7·5	1·92	·29	4·79	4·64	28	26	27
4.	3·70	4·3	1·16	·16	4·75	4·57	56	61	60
5.	4·10	7·4	1·81	·26	—	—	30	31	35
6.	4·00	7·5	1·88	·27	—	—	30	28	32
7.	3·75	7·9	2·11	·35	—	—		Genuine.	

The analyses marked 2 to 7 were made upon mixtures the composition of which was unknown to the operator, those marked 2 to 4 being the work of one of us (R.), those marked 5 to 7 of the other (B.). The results arrived at by analysis are given in the columns marked "calculated," and the agreement between the two methods and with the actual composition is extremely satisfactory.

THE ESTIMATION OF MILK-SUGAR IN MILK.

By H. Droop Richmond and L. Kidgell Boseley.

We have been in the habit of estimating the milk-sugar in milk by the method described by Vieth (Analyst, xiii. 63); this is a slight modification of that worked out by Wiley (*Amer. Chem. Jour.*, vi., 289), and the novelty in it consisted of the making of corrections for volume of fat, etc.

Vieth's method of calculation is founded on the following assumptions: (*a*) That the volume of proteids in 100 c.c. is 3·0 c.c.; (*b*) that the volume of fat in 100 c.c. is the percentage of fat divided by ·93.

This last assumption is not strictly correct, the volume of fat being the percentage of fat multiplied by the specific gravity of the milk and divided by ·93, but the error is very small. It is usually sufficient to multiply the percentage of fat by 1·11 to obtain the volume in 100 c.c. of milk.

Wiley and Ewell have recently published (Analyst, xxi., 182) a method for the estimation of milk-sugar in milk by double dilution and polarization; they make up 65·82 grammes of milk to 100 c.c. and 200 c.c. respectively, precipitate with acid mercuric nitrate and polarize the filtrates.

If a equal the reading from the 100 c.c. solution, and b the reading from the 200 c.c. solution, the correct reading will be $\frac{ab}{a-b}$ and the volume of the precipitate $\frac{100\,(a-2b)}{a-b}$.

A series of thirteen experiments to prove the correctness of the method is given, and the volume of the precipitate is calculated in each case; from the series it is concluded that "this correction is less in quantity than the combined volume of the fat and albuminoids." It appears, however, on recalculation of their figures, that the volume of the precipitate is wrongly calculated, the formula $\frac{100\,(a-2b)}{b}$ having been apparently used instead of the correct one given in their paper, and reproduced above.

In the table opposite Wiley and Ewell's figures are reproduced, the volumes of the precipitate being calculated by the correct formula; the volume of the precipitate is also calculated by Vieth's method.

It is seen that, though the average of the two methods agrees well, there is a fairly wide divergence between individual results. A comparison of the polarimetric figures of Nos. 1 and 9 will demonstrate that this divergence is chiefly due to the large experimental error of Wiley and Ewell's method. In these two it happens that the polarization in the 100 c.c flask is the same, while the polarization in the 200 c.c. flask differs only by ·07, which is within the limits of reading; this difference of polarization makes 1·5 c.c. difference in the volume of proteids. It also makes a difference of ·07 per cent. in the percentage of milk-sugar, while, had Vieth's method been used, a difference of ·07° would make a difference of less than ·02 per cent. To obtain the accuracy recorded, Wiley and Ewell found it necessary to use a very

		Mean ...	...	... 5·7	5·5	

delicate polariscope with tubes 400 m.m. long; with a less delicate polariscope and shorter tubes, the experimental error would be correspondingly magnified.

We can only conclude that this method is practically useless, on account of the large experimental error, the waste of time, and large amount of sample required.

The only objection to Vieth's method is that it is necessary to make a calculation for each sample, which, when several determinations are made at once, is apt to become tedious. To dispense with the calculation, we propose to add to each 100 c.c. of milk:

(*a*) Three c.c. of acid mercuric nitrate to compensate for the volume of the proteids.

(*b*) (Fat + 1·11) c.c. to compensate for the volume of the fat.

(*c*) One-tenth of the degrees of specific gravity.

(*d*) A sufficient volume to reduce scale readings to percentages of milk-sugar.

With the instrument we use [the Mitscherlich half-shadow polariscope, described by Vieth (ANALYST, xi. 141)], *d* is 10·0 c.c. to 100 c.c of milk; it may be calculated for other instruments by the formula $\left(\frac{55{\cdot}3\,K \times l}{100} - 100\right) \times S$ where K = factor necessary to convert angular degrees into scale readings, l = length of tube used, and S = specific gravity of the milk (which may be taken as 1·032 without appreciable error).

If the fat was 3·7, and the specific gravity was 1·0325, then $3 + 4{\cdot}1 + 3{\cdot}25 + 10 = 20{\cdot}35$ c.c. must be added to 100 c.c. of milk, or 10·17 c.c. to 50 c.c.

We have noticed the fact pointed out by Wiley and Ewell, that the stronger mercuric nitrate solution prescribed by Wiley is liable to discolour the proteids, but we cannot agree with them that it is the xantho-protein reaction; it is more properly described as Millon's reaction. We find it advantageous, however, to use their weaker solution, and add 15 c.c. of this to 100 c.c. of milk, making up the bulk with water.

* These figures are volumes of sand actually added.

A few test analyses are appended to show that accurate results can be obtained by dilution to obtain direct readings.

				Direct	Dilute	Milk Sugar.		Volume of Precipitate.	
Obs.	Sp. Gr.	Fat.	Dilution.	Polarimetric Reading.		Veith.	Wiley and Ewell.*	Veith.	Wiley and Ewell.*

We have also experimented with the action of various preservatives added to milk in the proportion of 1 gramme per 100 c.c. (except in the case of formalin where 2 c.c. were accidentally added); the samples were allowed to stand a week in an incubator at 25°.

	Polarization.
Original milk	5·63°
1 c.c. Chloroform per 100 c.c.	5·61°
1 gr. Borax per 100 c.c.	5·50°
2 c.c. Formalin per 100 c.c.	5·62° (corrected for dilution).
1 gr. Salicylic acid per 100 c.c.	5·61°
1 gr. Mercuric chloride per 100 c.c. ...	5·59°

With the exception of borax, it is seen that all the preservatives prevented any change.

Discussion.

The President (Dr. Dyer) said that among the many valuable papers in the old volumes of The Analyst a very prominent place must be given to those which emanated from the laboratory of the Aylesbury Dairy Company in the days of their old friend Dr. Vieth, and it was very pleasurable year by year to find Mr. Richmond carrying on this work, and bringing before the Society the results of his very large experience.

One little point which he noticed in the first paper was the high proportion of ash in two of the abnormal samples of milk. His own experience, and probably that of many others, showed that, when milk gave an abnormally low percentage of total solids, the ash was usually high, at once pointing out the abnormality of the samples, so that they were not easily confused with watered samples.

He was much interested in Mr. Richmond's remarks with regard to the nitrogen in decomposed samples, because he had lately heard from another member of the Society (Mr. Smetham, of Liverpool) that that gentleman had been making a somewhat extensive series of experiments on the value of the nitrogen factor in dealing with decomposed milks. He had not seen all Mr. Smetham's figures, but as far as

* We have, by calculating from our own figures, exaggerated the errors of Wiley and Ewell's method; roughly speaking, we have about doubled the experimental error.

the results had gone some time ago, Mr. Smetham had found that the nitrogen remained remarkably constant. It might be converted into different nitrogenous compounds, but it stayed in the milk, and did not seem to be lost in the form of free nitrogen. He thought that Mr. Smetham would have some results shortly to bring before the Society on this subject.

With regard to sterilized milk, he did not know whether it was suggested by Mr. Richmond that the presence of sterilized milk in ordinary milk was a thing to be deprecated, or regarded as an adulteration. Sterilized milk was generally considered to be a valuable article. It would probably be more interesting to the public to be able to detect the presence of unsterilized milk in milk that was supposed to be sterilized, but to this one would take a shorter cut by making a bacteriological examination.

Mr. ALLEN observed that the multitude of figures which had been placed upon the blackboard, and which, after all, only represented a fraction of the results actually obtained, was a sufficient indication of the vast amount of work the authors of these papers had got through; and as a Society, they were very much indebted to Mr. Richmond and Mr. Boseley for laying before them these results, which had now become a very welcome annual institution, the absence of which would be greatly missed. It was interesting to learn that Dr. Vieth's method for the determination of milk-sugar was able to hold its own with more recent modifications of the process. He had a high opinion of Wiley and Ewell's method; but if the use of a specially delicate polarimeter was essential, it militated greatly against the employment of the method in practice.

Dr. EDMUNDS raised the question whether sterilized milk, and, in fact, all sterilized foods, did not lose some of their vitalizing properties, especially for young children.

Dr. RIDEAL said that he was about to make a similar remark to that made by Dr. Edmunds. He usually lived in the country, but for the last two or three months he had resided in town. It was hardly a chemical matter, but in the country they were in the habit of keeping the milk overnight for the cream to rise. On coming up to London, however, the milk was supplied by a dairy company, and it was found that the cream of this London milk would not rise on standing, which seemed to point to the fact that the mixed milk had not the property of rising as pointed out in the paper. He thought that a consumer buying milk should reasonably expect it to throw the normal amount of cream on standing.

He did not think that either sterilized milk or humanized sterilized milk had the same value as unsterilized milk, which was probably due to the fact that the ferments present had lost their activity. He had been trying humanized milk from the same firm for a week or two, with results that were not satisfactory, but which were improved by the addition of a small quantity of unsterilized cow's milk, which probably supplied the missing ferment, if such were necessary, without materially altering the composition.

With regard to sour milks, he thought that the points referred to by Mr. Richmond ought to be made widely known, as they indicated an easy method of

ascertaining with certainty the composition of sour-milk samples. If a Lister-Babcock machine was used for determining the fat, a Kjeldahl determination could possibly be made on a fair average sample taken from the comparatively large quantity in the machine.

Mr. HEHNER said that the remarks of Dr. Edmunds and Dr. Rideal, which raised some doubt as to the food value of sterilized milk, had a serious aspect in view of sanitary considerations. If there were not any very strong evidence that by sterilization some material damage was done to milk, such statements might do unintentional harm. There was no chemical or physiological evidence whatever, as far as he was aware, that milk did contain any ferment necessary to digestion.

Mr. Richmond had omitted to mention the fact that calcium citrate was deposited from milk on boiling. In condensed unsweetened milks, a notable sediment of citrate existed; and this deposition might perhaps be another means of distinguishing boiled from raw milk. The change in the rate at which the cream rose was a very interesting fact. Whatever the explanation might be, it seemed to him that the viscosity of the milk had become altered. He had thought of using the viscosity of the milk as a rapid means of dairy analysis; but Mr. Richmond's results seemed to show that this would not be possible, except, perhaps, in the case of milks which it was certain had not been boiled. There were, other things being equal, two factors influencing the viscosity of milk—namely, the amount and size of the fat globules, and the amount of solids-not-fat. If the specific gravity and the viscosity, as measured by the rapidity of the flow through a narrow orifice, were determined, which could be done in a minute or two, some useful data might probably be obtained.

Mr. C. G. MOOR, with reference to the question of the adulteration of ordinary milk with unsweetened condensed milk, remarked that there was only one brand of unsweetened condensed milk sold in London to any extent, which was of Italian manufacture, and contained much less fat than it should if made from whole milk, and it contained a large addition of borax or boric acid.

Mr. BEVAN remarked that Mr. Richmond had mentioned only three abnormal samples, and desired to know whether they were the only ones he had met with during the year. He was interested in the President's remarks as to the ash, which showed the very great importance of always determining this, and being guided by it in forming an opinion. With regard to the nitrate test, he had been under the impression that Mr. Richmond had some time ago made experiments in this connection, and had found that nitrates might find their way through the medium of food into the milk in a perfectly normal manner.

Mr. RICHMOND said that the detection of diluted condensed milk in ordinary milk had been considered of such importance by the British Dairy Farmers' Association, that some years ago that Association had offered a gold medal for the publication of a method. Within the time during which the offer held good no method was discovered, but Mr. Faber had since brought out an excellent, and perhaps the best, method. He (Mr. Richmond) and his colleague had also studied the subject, and they thought it might still have sufficient importance to be worthy of consideration. Some years ago he (Mr. Richmond) had read a paper on the discrimination between abnormal and adulterated milks, in which he pointed out that a high ash was charac-

teristic of abnormal milks, and it afforded him much gratification that this was confirmed, as it had been, by the President and by Mr. Bevan. He might say that these three abnormal samples were the only ones that had come under his notice during the year. The question raised by Dr. Edmunds of the physiological effect which sterilization had upon milk was one of extreme importance, and one upon which it was hard to get reliable evidence. The opinions held and positive evidence adduced by medical men on this question were often absolutely contradictory; it was not one, however, which fell within the province of analysts. With regard to Dr. Rideal's remarks on the difference between country and London milk in the matter of the rising of the cream, it certainly was a widely-known fact that milk taken warm from the cow, and set immediately, gave more cream than if it were cooled down to a sufficiently low temperature to keep it for some hours, and not only was the quantity of cream larger, but the cream itself was much thicker. There had been one ferment described as present in milk, namely, the galactozymose of Béchamp, but this observer was the only person who had met with it, and his observations had not yet received confirmation. They had purposely omitted any mention of calcium citrate. They had thought of making some remarks on this subject, but on considering the matter, and making experiments in connection with the estimation of citrates, they found that it was not an easy thing to do, and were unable to get any results of real value, so they thought it best not to fill the paper with points that could only be just touched upon. With regard to the viscosity of milk, he did not think that this factor was likely to be of much use for analytical purposes, as it involved calculations of an extremely complicated character. The viscosity of milk was due to, first, the internal friction of the molecules of the aqueous portion, and, second, to the friction between the fat globules and the serum, and very small variations of conditions might and did affect the ratio of the separate effects of friction.

The PRESIDENT said that the Society's thanks were due to Mr. Richmond and Mr. Boseley for these papers. Even if there did not appear to be any immediate practical object in detecting the presence of sterilized milk, the results obtained were none the less interesting and valuable. The Society was a technical, but not altogether a utilitarian, Society, and always valued facts. Besides, even though the practical application of such facts might not be immediately apparent, there was always the possibility that they might ultimately prove useful.

FOOD AND DRUGS ANALYSIS.

Distinction between Raw and Boiled Milk. I. Carcano. (*Giorn. di Farm. di Trieste*, 1896, i., 275; through *Chem. Zeit. Rep.*, 1897, 46.)—The sample is warmed gently with a few drops of fairly fresh oil of turpentine and an alcoholic solution of guaiacum added. The appearance of the well-known blue colour shows that the milk has not been boiled, and *vice versâ*. E. H. L.

The Detection of Horseflesh in Sausages, etc. H. Bremer. (*Forsch. Ber.*, 1897, iv., 1-8.)—The various methods which serve for the detection of horseflesh are based either on the glycogen reaction or on an examination of the fat (see ANALYST abstracts, xix., 24; xx., 95 and 252; and xxi., 231). The author gives a summary of the work of others in this direction, and then describes his process, which consists in an examination of the intra-muscular fat.

The meat preparation, from which all visible fat has been removed, is minced in a sausage-machine, and heated for about an hour on the water-bath with water. The fat rising to the surface is poured away with the water, and the flesh, after having been washed several times with hot water, is dried at 100° C. for twelve hours, and extracted for several hours with a petroleum spirit of low boiling-point. Part of the intra-muscular fat thus obtained is taken for the determination of the iodine number, refractive index, and Reichert-Meissl number. The remainder is saponified, the excess of alkali neutralized with acetic acid, and the alcohol evaporated on the water-bath. The soap is dissolved in hot water, a hot solution of zinc acetate (1 part to 2 parts of fat) added, and the zinc soap washed with hot water and alcohol, pressed between filter-paper, and extracted with about ten times its volume of water-free ether for fifteen to thirty minutes under a reflux condenser. After cooling, the solution is filtered into a weighed flask, the ether evaporated, and the iodine number of the residue determined. Every precaution must be taken to prevent access of air during filtration and drying.

The subjoined table gives the results obtained by this method:

	Iodine No. of Intra-muscular Fat.	Iodine No. of Liquid Fatty Acids.
I. Horseflesh sausage without bacon	75·8	108·1
II. Horseflesh sausage with about 6 per cent. of bacon	74·0	104·1
III. Horseflesh cervelat sausage with about 22 per cent. of bacon, well smoked ...	53·7	92·4
IV. Horseflesh cervelat sausage with about 25 per cent. of bacon	74·1	102·1
V. Ordinary sausage with some bacon ...	57·6	94·2
VI. Thuringian cervelat sausage with about 65 per cent. of pig's fat	64·3	95·8
VII. Mixture of I. and V. in equal parts ...	66·4	103·1
VIII. Mixture of IV. and VI. in equal parts ...	65·2	99·5

It is stated that whenever horseflesh is present the petroleum spirit extract has a red to reddish-brown colour, and that even the liquid fatty acids have a more or less reddish-yellow shade. On the other hand, bull's flesh gives a similar colour, so that too much reliance must not be placed on this fact, except as a confirmatory test. When, however, this is found to be the case, when at the same time glycogen is detected, and when the iodine number of the intra-muscular fat exceeds 65, and that of the liquid fatty acids is considerably over 95, there can be but little doubt as to the presence of horseflesh. C. A. M.

Detection of Caramel in Wines—Possible Confusion with the Coal-tar Colours. A. J. Da Cruz Magalhaes. (*Comptes rendus*, cxxiii., No. 21; through *Chem. News.*)—The author found that a caramelized Portuguese liqueur wine responded to the general reactions of coal-tar colours: dyeing mordanted wool in presence of potassium sulphate; forming in presence of lead subacetate an orange-yellow liquid, which yielded up its colouring matter to amyl alcohol, a similar reaction occurring with ammonia in excess, and turning orange-yellow when agitated with yellow mercury oxide. Identical results were obtained with another wine colored with pure caramel from ordinary sugar, as well as in the case of solutions of pure caramel.

Caramels from pure dextrose (1) and saccharose (2) were also tested, with the following results:

Treated with lead basic acetate and amyl alcohol: (1) No coloration; (2) deep orange-yellow.

Supersaturated with ammonia and taken up with amyl alcohol: (1) Greenish-yellow; (2) very deep orange-yellow coloration.

Ether: (1) No coloration; (2) orange yellow.

Mordanted wool: (1) Dyed yellow; (2) orange yellow.

No alteration of the original colour of the solutions was produced by Cazeneuve's test. C. S.

Quantitative Examination of Crude Woody Fibre. Lebbin. (*Arch. Hyg.*, 1897, xxviii., 212; through *Chem. Zeit. Rep.*, 1897, 45.)—This process depends on the fact that ammoniacal hydrogen peroxide dissolves starch and vegetable albumins, but leaves pure cellulose practically untouched. 3 to 5 grammes of the meal or bran are very finely powdered and boiled for half an hour in a large beaker with 100 c.c. of water; 50 c.c. of 20 per cent. hydrogen peroxide are next added, and the boiling continued for twenty minutes, while 15 c.c. of 5 per cent. ammonia are gradually dropped in. The whole is boiled for a further twenty minutes, thrown on a tared filter, and the insoluble matter washed with hot water, dried and weighed. From the residue the weight of ash must be deducted, and also 6·25 times the amount of nitrogen it contains, if there be much present. The process gives uniform results, and the solutions filter well. F. H. L.

ORGANIC ANALYSIS.

Test for Formaldehyde. L. Kentmann. (*Pharm. Gen. Anz.*, 1896, viii., 356; through *Chem. Zeit. Rep.*, 1896, 313.)—If the suspected liquid is floated on an equal volume of a solution of 0·1 gramme of morphine hydrochloride in 1 c.c. of strong sulphuric acid, a red violet colour is produced within a few minutes, provided the formalin exceeds one part per 6,000. F. H. L.

Estimation of Furfuraldehyde by Means of Phloroglucinol. 1. **C. Councler** (*Chem. Zeit.*, 1897, xxi., 2); 2. **C. Krauch** (*loc. cit.*, p. 29).—This is primarily a discussion on the suitability or otherwise of Merck's preparation, "Phloroglucin. puriss. pro anal. (m.p., 210° C.)," for the purpose indicated. On the authority of Krüger and Tollens, Krauch has stated in the last edition of his book, "Die Prüfung der Chemischen Reagentien auf Reinheit," that it is sufficiently pure to be so employed; but Councler holds that it varies greatly in composition, and often contains enough diresorcinol to vitiate the results. He therefore considers it necessary always to use a preparation freed from this impurity by Skraup's method.

The remainder of Councler's paper is also largely polemical, and deals with the modifications of his process, which have been suggested by Krüger and Tollens (*Zeits. angew. Chem.*, 1896, 40). He maintains that it is preferable to wash the precipitate till free from chlorine, and then to dry it to constant weight, rather than to wash with 150 c.c. of water, and to dry at 100° for three or four hours only; and that it is better to add the phloroglucinol in the solid form, in order to keep the volume of liquid as small as possible. He also discusses at some length the question of precipitating the whole of the furfural distillate, or only an aliquot portion thereof, and decides that, in the majority of cases, the latter procedure suffices.

F. H. L.

Gravimetric Estimation of Sugar. G. Ambühl. (*Chem. Zeit.*, 1897, xxi., 137.)—The author recommends that the cuprous oxide produced in the Fehling-Allihn process should be dried for one hour at 98·5° C., and weighed as such, instead of being reduced to the metallic state. He presents an elaborate table, showing the results of the method when applied to forty-six samples of wine, honey, and diabetic urine. In the case of wines, the figures are practically identical with those obtained by weighing the metal, being usually a trifle higher (maximum, +0·09; average, +0·034 per cent.). With honey, the excess averages 0·23 per cent. on amounts of sugar varying from 57 to 69 per cent.; and with urine containing 4·25 to 6·16 per cent. of sugar, the mean difference between the two processes is 0·10 per cent., but in this instance the suboxide was manifestly contaminated with organic substances, which suffer decomposition on ignition. F. H. L.

A spontaneously Inverting Cane-sugar Solution. A. Lam. (*Chem. Zeit.*, 1897, xxi., 56.)—The author has recently examined a sample of English crude sugar which was suspected of adulteration. Immediately after solution it gave in Laurent's

polarimeter a value of +91·0, but in twenty-four hours this fell to 80·5, continuing to alter till after ten days its opticity was +12·5, and after thirty days −24·5 (at which point it remained constant). Titrated with Fehling's solution after standing twenty-four hours, the sample appeared to contain 17 per cent. of reducing sugars (calculated as glucose); but on inverting it according to Clerget's method, the figure (−33·8 at 16·5° C.), taken in conjunction with the positive rotation of 91, showed that it actually contained 92 per cent. of true cane-sugar. Further investigation proved that the anomalous behaviour of the material was due to a rod-shaped micro-organism possessing the property of inverting faintly acid and saline solutions of sugar, but without influence on such as are neutral, alkaline, or free from salt. F. H. L.

The Detection and Extraction of Citric and Malic Acids by Means of Quinine and Cinchonine. L. Lindet. (*Bull. Soc. Chim.*, 1896, 1160-1163.)—Citric and malic acids may be easily distinguished by the difference in solubility in methyl alcohol of their quinine and cinchonine compounds, and on this difference the author has based a process for extracting them from vegetable juices.

Cold methyl alcohol (95 per cent.) dissolves only 0·3 per cent. of acid citrate of quinine and 3·3 per cent. of the neutral citrate, while the corresponding malates are soluble to the extent of about 8 per cent. The presence of malic acid interferes with the precipitation of the acid citrate of quinine, and when, in a mixture of the two acids, the quantity of malic acid is 25 per cent. of the quantity of citric acid, not more than 99 per cent. of the theoretical acid citrate of quinine is obtained. When the proportion of malic acid is increased to 50, 100, and 200 per cent., the quantities obtained respectively are 97, 94, and 83 per cent. Under the same conditions the acid oxalate of quinine (solubility 9·2 per cent.) and the neutral oxalate (solubility 8·2 per cent.) remain in solution, but these also increase the solubility of the quinine citrate.

Cinchonine dissolved in methyl alcohol precipitates malic acid where quinine precipitates citric acid. The solubility of the acid malate of cinchonine is 2·5 per cent., but the other salts of cinchonine are so soluble that the precipitation can be considered as characteristic of malic acid. The acid tartrate of cinchonine dissolves to the extent of 26 per cent., whilst the acid citrate, the acid oxalate, and the acid succinate only crystallize when their solution is evaporated to a syrupy consistency. The presence of tartaric, citric, oxalic, or succinic acids considerably increases the solubility of cinchonine malate in methyl alcohol.

In applying these reactions to the extraction of the acids from vegetable juices, the latter must be evaporated in vacuo, and the residue taken up in methyl alcohol (as concentrated as possible). Tartaric acid, if present, should be removed by adding alcohol and ether and precipitating with potash. The excess of potash is eliminated by precipitating all the acids with subacetate of lead, and afterwards liberating them by sulphuretted hydrogen. This is the method to be adopted when the juice contains much sugar or foreign matter. Tannin must also be removed by absorption with animal matter, such as catgut.

The concentrated acids are dissolved in methyl alcohol, and to a definite quantity

of the solution, containing about 2·5 per cent. of acid, quinine as a powder is added little by little, until after shaking for some time a crystalline precipitate is produced. The quantity of quinine added must not exceed 160 to 170 per cent. of the quantity of supposed citric acid, or the more soluble neutral citrate of quinine will be produced. When the proportion of quinine has been established, the main solution is treated with the calculated amount. After standing for twenty-four hours, the liquid is filtered, and the operation repeated on the mother liquor.

When no precipitate is obtained—that is, when citric acid is absent—malic acid is tested for and extracted in the same way, the maximum amount of cinchonine to be added being 140 to 150 per cent. of the supposed quantity of malic acid. Where the two acids are present together, cinchonine is added to the liquid after precipitation with quinine, since an excess of the latter does not interfere with the precipitation of cinchonine malate.

The acids are easily recovered from the alkaloidal salts by adding ammonia to their aqueous solution, filtering from the alkaloids, precipitating the acids with sub-acetate of lead, and decomposing the precipitate with sulphuretted hydrogen; or the acid may be removed by barium hydrate, the precipitate, after drying, being washed with alcohol, and finally decomposed with sulphuric acid.

In this way the author has extracted the citric acid from the juice of lemons, gooseberries, strawberries, raspberries, and tomatoes, and the malic acid from that of cherries and grapes. C. A. M.

The Iodine Number of Cocoa-Butter. D. Holde. (*Zeits. anal. Chem.*, 1897, xxxvi., 163, 164.)—In an abstract of the work of De Negri and Fabris, "Gli Olii," which was published by the author in the *Zeits. anal. Chem.*, xxxiii., 570, the higher limit for the iodine number of cocoa-butter was given as 51. This high value led Strohl to examine specimens of all the different varieties of the fat (ANALYST, xxi., 231), and the highest figure he could obtain was 41·7. Then Filsinger published a note (ANALYST, xxii., 46), in which he suggested that Strohl's higher limit (41·7) might have been due to the presence of free fatty acids, since in his work with Henking in 1889 he had not found a higher value than 37·5. With regard to this opinion, the author points out that Strohl obtained an iodine number of 39·8 to 40·4 with specimens of fresh cocoa-butter, and that, as he himself has found in the case of fluid fats, and as Späth (ANALYST, xxii., 46) showed in the case of lard, an increase of acidity is accompanied by a decrease in the iodine number. These various communications have led the author to refer to the original paper of Hübl, from whom De Negri and Fabris took their figures for cocoa-butter, and he now finds that those chemists wrongly transcribed the value 51, which in Hübl's paper is 34. C. A. M.

Estimation of Rosin in Fats and Soaps. J. Landin. (*Chem. Zeit.*, 1897, xxi., 25.)—In the hands of the present author, Twitchell's process is perfectly satisfactory; but he prefers to use petroleum spirit instead of ether as the solvent for the resin acids, and also to determine them gravimetrically, owing to the uncertainty

about their true molecular weight. As regards Cornette's process (ANALYST, xxi., 260), sodium resinate is not really soluble in saturated sodium chloride. If an alkaline solution of rosin containing 2 per cent. of colophony is treated gradually with this liquid, the first precipitate disappears, until an equal volume of salt solution has been added, but further additions again increase the amount of insoluble matter. The method is, therefore, not reliable. F. H. L.

Valuation of Glue by Viscosimetry. J. Fels. (*Chem. Zeit.*, 1897, xxi., 56 and 70.)—None of the methods hitherto proposed for testing glue can be deemed trustworthy; and even Stelling's (ANALYST, xxi., 239) is inexact. An exception must perhaps be made in favour of Lipowitz's plan of judging the material according to the consistency of the jelly it yields on treatment with a definite amount of water; but, still, this only gives comparative results. The present investigator holds that by determining the viscosity of a glue solution in Engler's apparatus the actual adhesive power of the substance can be gauged, and, moreover, the figures obtained may be expressed in an absolute form. The process has been in use for a year, and has proved quite satisfactory.

The sample is rubbed to powder, and the moisture estimated by drying it at 100° for two hours: 100 grammes are soaked in about 400 c.c. of cold water for twenty-four hours, melted on the water-bath, and the amount of liquid so adjusted that the solution contains 15 per cent. of dry glue. It is then tested in the viscosimeter at 30° C., the time taken for an equal volume (500 c.c.) of water to run out being considered as unity. Treated in this way, five samples gave the figures: 1·36, 1·60, 1·65, 1·91, and 2·21; and it was found that the values expressed the same differences in quality as were deduced from an examination of the corresponding jellies according to Lipowitz's method. F. H. L.

Mineral Constituents of the Water-Melon. G. F. Payne. (*Jour. Amer. Chem. Soc.*, 1896, xviii., 1061-1063.)—Two medium-sized water-melons cut up and mixed together were found to contain just ½ per cent. of pure ash calculated as free from carbonic acid. The composition of the ash was:

	Per cent.
Sulphur trioxide	4·41
Calcium oxide	5·54
Magnesium oxide	6·74
Potassium oxide	61·18
Sodium oxide	4·31
Silicon dioxide	2·15
Phosphorus pentoxide	10·25
Chlorine	4·94
Iron sesquioxide	0·48
	100·00

C. A. M.

INORGANIC ANALYSIS.

The Separation of Bismuth from Lead. A. L. Benkert and E. F. Smith. (*Jour. Amer. Chem. Soc.*, 1896, xviii., 1055, 1056.)—Herzog (*Zeit. anal. Chem.*, xxvii., 650) has described a method of separating bismuth from lead by precipitation of the former as basic acetate, but the authors consider the method too tedious, and not entirely satisfactory in its results. They have substituted a formate solution for that of the acetate with satisfactory results.

Solutions of lead nitrate and bismuth nitrate in nitric acid were prepared containing in 20 c.c. 0·2076 gramme of lead oxide and 0·1800 gramme of bismuth trioxide respectively. Twenty c.c. of each were mixed in a beaker, nearly neutralized with sodium carbonate, and an excess of sodium formate solution (specific gravity 1·084), and a few drops of aqueous formic acid were added. The total dilution of the liquid was 250 c.c. It was boiled for *five* minutes, the precipitate allowed to settle, and the solution filtered while hot. The basic formate, which rapidly separated when not boiled too long, was washed with hot water, dissolved in dilute nitric acid and precipitated with ammonium carbonate. The ignited bismuth trioxide weighed too much, which was found to be due to lead; but on dissolving the impure oxide in nitric acid and *repeating the precipitation* as basic formate, the results obtained in eight determinations varied from 0·1796 gramme to 0·1806 gramme of bismuth trioxide, as compared with the theoretical 0·1800 gramme.

With a solution containing 0·3600 gramme of bismuth oxide and 0·2076 gramme of lead oxide, two results were obtained—0·3595 gramme and 0·3605 gramme of bismuth trioxide. C. A. M.

Detection and Estimation of Minute Traces of Lead in Waters. J. C. Berntrop. (*Chem. Zeit.*, 1896, xx., 1020.)—The sample, without concentration, is treated with a sufficient quantity of sodium phosphate, the whole well shaken and allowed to rest for twenty-four hours. The precipitate is collected on a filter, dissolved in a little nitric acid, the liquid evaporated on the water-bath till most of the acid has been driven off, and then subjected to the action of sulphuretted hydrogen, If this produces a coloration only, the lead may be determined colorimetrically; otherwise the precipitate may be redissolved in nitric acid and the metal estimated in the usual manner. Three test solutions were prepared, containing 0·1, 0·025, and 0·5 parts of metallic lead per million; both of the former gave a very distinct colour. and in the latter the lead was determined with great accuracy. If the original water is very soft, some calcium chloride should be added before the sodium phosphate.

F. H. L.

Estimation of Manganese in Iron and Steel. L. Schneider. (*Chem. Zeit.*, 1897, xxi., 41.)—If a solution of potassium permanganate containing about 20 milligrammes of manganese is mixed with 300 c.c. of 1 : 2 nitric acid, reduced with a ferrous salt, heated to the boil, and then a small spoonful of lead peroxide added, the reoxidation is instantaneous and complete. This may be proved by cooling the whole rapidly, and filtering through asbestos, when the theoretical quantity of permanganic acid will be found in the filtrate on titration with hydrogen peroxide. It is therefore

evident that the amounts of manganese obtained in nitric acid solution during the analysis of steel may be oxidised to the state of permanganic acid, and estimated volumetrically in a few minutes instead of "hours" (*cf.* Rürup, ANALYST, xxi., 218).

F. H. L.

Estimation of Sulphur in Pyrites with Sodium Peroxide. C. Glaser. (*Chem. Zeit.*, 1897, xxi., 40.)—In carrying out this process—especially when the peroxide is old and damp—it often happens that the insoluble portion of the melt is coloured black, owing to the re-formation of ferrous sulphide from some sodium sulphide present. In such a case it is not necessary to reject the analysis, for the oxidation may be completed in the wet way. The basin and its contents should be cooled somewhat, covered over, and more sodium peroxide added by degrees until the residue becomes brownish red, and a persistent froth appears. The ferric oxide should be washed with boiling water by the aid of the pump; and, as it is easily soluble in brominated hydrochloric acid, it can be tested for sulphuric acid, and the barium sulphate, if any, added to the main precipitate.

Von Asboth has stated that in treating low-grade pyrites (30 per cent.) the barium sulphate may be contaminated with silica, and that it is advisable, therefore, to remove this before introducing the barium chloride. This trouble does not occur with American ores containing 40 to 45 per cent. of sulphur; at least, if the liquid is not allowed to stand after precipitation longer than is required for the barium sulphate to subside (fifteen minutes). F. H. L.

Determination of Meta- and Pyro-Phosphoric Acids in Dried Superphosphates. Piron and Nay de Mézence. (*Ann. de Chimie Analyt.*, ii. [1], 4-6.)—Owing to the non-indication by the official (ammonium citrate) method of superphosphate analysis of the meta- and pyro-phosphoric acid formed from a portion of the orthophosphate during the drying of the product, manufacturers are disinclined to adopt this method, since it reduces the market value of the article. Having found that the meta and pyro-modifications can be rapidly reconverted into the ortho- form by the aid of heat in the presence of nitric acid or an alkali, the authors propose to modify the official method as follows: 2·5 grammes of pulverized superphosphate are digested for twelve hours with ammonium citrate; then made up to 250 c.c. and filtered, 100 c.c. of the filtrate being saturated and made decidedly acid with nitric acid, heated to near boiling for an hour, and precipitated in the usual manner when cold. The difference between the amount of phosphoric acid so determined and that arrived at by the ordinary method, gives the percentage of pyro and metaphosphoric acids in the superphosphate. C. S.

APPARATUS.

An Improved Capped Reagent Bottle. (*Chem. Zeit.*, 1897, xxi., 139.)—The stopper of this bottle is made of the usual flat-headed shape, but it is hollowed out on the top, thus forming a receptacle wherein hygroscopic or other materials can be placed in order to preserve the contents from moisture or carbon dioxide. The cap fits on the outside of the neck of the vessel in the ordinary manner. It is claimed

that this device prevents the stopper from becoming fixed, and that it is not necessary to grease it. By filling the receptacle with formalin, the bottle may also be employed as a sterilizing apparatus. F. H. L.

LEGAL.

PROCEEDINGS UNDER THE FOOD AND DRUGS ACT.

THE SALE OF ADULTERATED GLYCERIN.

(Reprinted from the "Pharmaceutical Journal" of February 27, 1897.)

AT the Birmingham Police Court, on the 19th inst.,* Frank Clent, of No 1, Cooksey Road, was summoned for selling glycerin not of the substance and quality demanded. The prosecution was conducted by Mr. Hiley (assistant Town Clerk), on behalf of the Health Department, and Mr. Philip Baker, solicitor, defended.

Mr. Hiley informed the Bench that, so far as he was aware, that was the first prosecution in Birmingham with reference to adulterated glycerin, and there were two summonses issued against two persons, who were wholesale druggists, charging them with selling glycerin largely adulterated with dilute glucose syrup. About the end of January, the inspector under the Food and Drugs Act found a considerable number of penny bottles of glycerin being sold in small shops, and inquiries revealed the fact that the article was in many instances supplied by the defendant. On February 4 a dozen bottles were purchased at defendant's shop, and on the article being analysed it was found to contain a large percentage of syrupy sugar, which, instead of possessing healing properties, had no medicinal value whatever. Each of the bottles was labelled "Pure Glycerin." After the summons was issued, defendant called at the Health Department, and admitted he knew the glycerin was adulterated, and asked that the proceedings might be stopped.

Annie Bennett spoke to purchasing a dozen bottles of glycerin from defendant, for which she paid 7d.

Inspector Jones and Chief-Inspector Parker deposed to conversations they had with defendant. Parker said that defendant told him he knew the glycerin was adulterated. Others were doing it, he said, and he was forced to do so.

Dr. Hill, the city analyst, said that the sample he received from Jones proved, on analysis to contain 45 per cent. of dilute glucose syrup, or syrup of starch as it was called. Glycerin * * * * * * * * was a drug endowed with active medicinal properties. It was used as a medicine itself, and as a vehicle for other medicines. Nearly one half of the sample he analysed consisted of the starch he had mentioned, which was a sugar artificially manufactured by chemical means from common starch. It possessed no medicinal properties, and was not a drug in any way. * * * * * * That described by him in his analysis would not be injurious. It would only have half its proper value.

Mr. Baker: Concerning the value, is it a fact that it would be very difficult to sell a bottle of pure glycerin at a penny?

Dr. Hill: Glycerin is cheap enough, about 8d. a pound. It is not a question of cost with me, it is a question of purity.

Mr. Baker asked the magistrates to deal leniently with the defendant, who, since the proceedings were taken against him, had had the misfortune to have his shop and uninsured stock destroyed by fire.

Mr. Ryland (Chairman of the Bench) said that although that might be the first case brought forward, they could not look upon it as the first case of adulteration. Even people possessed of no chemical knowledge must know they must not supply articles adulterated like the one in question. A penalty of £5 and costs was imposed.

* February 19.

THE ANALYST.

MAY, 1897.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

The monthly meeting of the Society was held on Wednesday evening, April 7, at the Chemical Society's Rooms, Burlington House, the President (Dr. Bernard Dyer) occupying the chair.

The minutes of the previous meeting were read and confirmed.

The following paper was read and discussed: "The Separation and Identification of the Typhoid and Colon Bacilli," by F. Wallis Stoddart.

A paper by Mr. J. F. Liverseege, entitled "Notes on Alcohol," was taken as read.

The following gentlemen were elected members of the Society: Mr. William Crowder, F.I.C.; Mr. John Heron, F.I.C.; Mr. L. de Koningh, F.I.C.; and Mr. A. H. M. Muter, A.I.C.

Mr. Richard Murray was elected an Associate.

NOTE ON WEIGHING OUT FATS.

By Charles E. Cassal, F.I.C.

(*Read at the Meeting, January* 13, 1897.)

In carrying out the Reichert process, it is obviously essential that exactly 2·5 grammes of butter-fat should be operated upon if comparative results are to be obtained in any two or more analyses of the same sample. I have reason to believe that this is not always done by those who have occasion to make analyses of butter, and I therefore mention the fact, although I do not think that the remark applies to any members of the Society. Weighing out, however, appears to be generally accomplished by difference: a dish containing the fat is weighed, and 2·5 grammes are taken out by a glass rod. Weighing by difference is inconvenient, and may easily be the cause of serious mistakes, especially when a large number of samples are under examination. I have used the thin porcelain boats, shown in the accompanying illustration, for directly weighing fats for a considerable time, and I find them to be very convenient. A number of them are ground to the same weight. The boat in which the fat is to be weighed

out is counterpoised by another, and the boat containing the fat is suspended in the neck of the distilling flask by a piece of glass rod, the fat being washed down by heating the alcohol which has been placed in the flask for the saponification.

DISCUSSION.

Mr. ALLEN asked where the porcelain boats could be obtained.

Mr. CASSAL said that they were made by Messrs. Baird and Tatlock. A special mould had been made for them, but this having been done, they could now be obtained fairly cheap.

Mr. STOCK asked if it was absolutely necessary that the boats should be ground to the same weight, or whether the use of a counterpoise was admissible.

Mr. CASSAL said there was no particular reason for their being all of the same weight, except that it saved trouble, and time also, when a number of things had to be weighed out. Of course a metal counterpoise could be used, but he preferred to have the boats all of the same weight.

THE SEPARATION AND IDENTIFICATION OF THE TYPHOID AND COLON BACILLI.

BY F. WALLIS STODDART.

(*Read at the Meeting, April* 7, 1897.)

THE triple problem which forms the subject of this paper has received an immense amount of attention at the hands of bacteriologists, but, as a whole, may at the present moment be fairly described as unsolved. It is true that the typhoid bacillus may now be identified with almost as much certainty as any other micro-organism when isolated in pure culture; but the essential preliminary of first catching the object of pursuit before submitting it to the process of scientific cookery known as cultivation is still little more than a matter of luck under the conditions usually prevailing.

I propose, first of all, to show that nothing better should be expected of the processes now in use; then to describe a method by which the typhoid bacillus can readily and certainly be separated from the colon bacillus, and from numerous other micro-organisms; and, lastly, to point out that the difficulty of identifying the colon bacillus is vastly greater than is generally supposed.

The carefully compiled *résumé* of processes presented lately to this Society by Messrs. Pearmain and Moor relieves me of the necessity of describing at any length the special methods recommended for this particular line of investigation. I may briefly remind you that, after the gelatin-plate process had been found to fail in consequence of the rapid growth of liquefying organisms, it was discovered that the addition of a small proportion of phenol obviated this difficulty; and from that time to the present phenolated media have played a large part in all attempts to isolate the typhoid bacillus, though it has been found necessary to largely reduce the proportion of phenol first used. Later it was suggested by Parietti that the simultaneous addition of hydrochloric acid effected a more complete suppression of interfering

forms, and for some years this modified process was almost universally adopted. It now seems to have fallen into disuse. Still later appeared the potato-gelatin method of Elsner, by which, perhaps, a more conspicuous difference in the naked-eye appearance of the colonies is created, but which retains the fundamental faults of older processes. Lastly, I should mention the proposal of Dr. Klein to concentrate the bacterial contents of a large quantity of water by filtration. The process in vogue at the present time is, then, as follows: The particulate matter collected by filtration through a Berkefeld bougie is distributed in (*a*) gelatin plates, or (*b*) broth tubes, both media having previously received an addition of ·05 per cent. phenol. Any growth in the tubes after incubation is then distributed upon agar or gelatin plates, and suspicious colonies in either series of plates are subcultured.

It is difficult to believe that a process which represents the combined work of so many investigators should tend to increase, instead of to diminish, the already nearly insuperable obstacles to success: yet a little consideration will show this to be the case. For a due appreciation of this it is necessary to bear in mind that the one great, if not insurmountable, difficulty is the presence in all polluted waters and similar materials of an immense number of micro-organisms not separable from typhoid except by plate culture, and not distinguishable except by one or more subcultures. These organisms, amongst which is *Bacillus coli*, are much more resistant to phenol than is the typhoid bacillus, which occupies an intermediate position in this respect between them and the more sensitive water bacteria. In common no doubt with most bacteriologists, I spent much time some years ago in endeavouring to develop this test, and I found that a very small proportion of phenol checked the growth of the typhoid bacillus, which refused to multiply in media containing more than about ·15 per cent. of either phenol or hydrochloric acid, or ·1 per cent. of each. On the other hand, a variety of organisms found in water grew in media containing up to ·3 per cent. phenol, and broth containing ·2 per cent. decomposed spontaneously if exposed for a few minutes to the air. It was evident that organisms possessed of this power of resistance to antiseptics are widely distributed, and would generally appear in abundance when the test is applied to polluted waters and the like. This conclusion accords with the published experience of others.

But there are other considerations which tend in the same direction. The typhoid bacillus multiplies under the most favourable circumstances much more slowly than the members of the group of which *B. coli* is the type. Grown in gelatin plate at 20° C. the colonies of typhoid are about twenty-four hours later in making their appearance. Cultivated in broth at 37·5° C., *B. coli* and its allies multiply from two to five times as fast as the typhoid bacillus. This difference in the growth rate, accentuated, of course, by the addition of phenol to the medium, operates in two ways: not only is the numerical superiority of the non-pathogenic forms materially strengthened, but in the final stage of plate culture valuable space is preoccupied in which typhoid colonies might otherwise develop. This is especially the case with the gelatin plate, where the most valuable portion—the surface—is largely occupied within twenty-four hours by the expanded colonies of *B. coli*.

Lastly, there is good evidence that some of the organisms commonly present in

polluted water will in broth culture inhibit the growth of typhoid. This is not the case with *B. coli*, the two forms apparently growing normally side by side; but with some species the double inoculation of broth results in the growth of the saprophyte only.

Now, it is easy to see that if it is a difficult and often impossible matter to find a few typhoid bacilli in the presence of a huge majority of saprophytic forms by the direct application of the plate process, there is very little chance of doing so when the natural tendency of the latter to improve their numerical superiority is fostered by the conditions of culture, and when the inhibitory powers possessed at least by some of them are allowed full play. Nor are matters at all improved by the preliminary concentration already referred to; for by this step no increase in the proportion of typhoid bacilli can be brought about. On the contrary, it is not unreasonable to suppose that the somewhat violent treatment may have a more injurious effect upon them than upon the hardier forms; and waters that call for examination in this way are almost certain to contain quite as many organisms as can be dealt with in plate culture without concentration. I quite admit the desirability of working upon a larger sample than the minute fraction of a cubic centimetre, which is the utmost one can often use in a single plate; but this must be done at present by increasing the scale of operations, and not by crowding an unmanageable number of organisms into a few plates.

This numerical difficulty has been fully appreciated by many investigators, and has been most forcibly presented by Messrs. Laws and Andrewes in their recent report.

Consider, for instance, the case of a moderately polluted water containing 50,000 microbes per c.c. Of these, possibly 90 per cent. may be suppressed by the addition of phenol, leaving 5,000 to be dealt with by plating out. There would obviously be no advantage in concentrating such a water, since it is impossible to deal satisfactorily with a plate of ordinary size containing 1,000 colonies. It would then be necessary to subculture every one of these colonies, for the naked-eye appearances are not to be relied upon.

On the other hand, if the water is cultivated in phenol broth, a greater proportionate increase takes place of *B. coli* than of typhoid, even if the latter is not suppressed altogether, and the plating-out process becomes less hopeful than before. Probably the most promising modifications of the current method are as follows: Cultivate in phenol-gelatin plate at 20° C. for twenty-four hours, photograph the plate, incubate again, and subculture any colonies that subsequently appear; or make plain agar plates, incubate at 37·5 per cent., and subculture every colony.

The utter hopelessness of the task has been brought home to me on several occasions on which I have unsuccessfully endeavoured to isolate the typhoid bacillus from waters which were beyond any reasonable doubt actually conveying the disease at the time, and which yielded abundant chemical evidence of sewage pollution.

Sharing the general impression which prevails as far as I can gather at the present time, that the key to the situation would be found in a more perfect separation of the typhoid from the colon bacillus, I addressed myself particularly to this point. It was obviously advisable to discard the use of antiseptics, to avail one's self of the almost equally complete suppression of water bacteria effected by cultivation at blood-heat,

to stimulate the growth of the typhoid bacilli if possible without forcing its companions, to remove the former as rapidly and completely as may be from the latter's influence, and to bring about a physical separation of the species. In fact, I set before myself as a model the *maass* culture, used so successfully in the case of the cholera spirillum.

Under the idea—I am speaking now of four or five years ago—that *B. coli* was a comparatively sluggish form, I thought the typhoid bacillus might be induced to walk away from a mixture of the two, and I naturally tried the well-known potato culture, in which the typhoid bacillus rapidly forms a thin, scarcely visible layer, whilst *B. coli* is almost confined to the point of inoculation. Many difficulties, particularly that of getting potatoes of uniform composition, induced me to look for substitutes; and I did actually effect a separation of the forms by moistening filter-paper, or a porous plate, with broth, inoculating the centre from a mixed culture, incubating, and making subcultures from various points nearer the circumference. There was, however, considerable difficulty in just keeping the paper moist without getting condensed water in local accumulations, and there was the further disadvantage of being unable to see what was going on. In my endeavour to find a transparent medium I came upon exactly what was required. I found that if any of the ordinary solid media were inoculated with typhoid, and incubated at a temperature at which it just maintained its consistence, the growth took the form of an opalescence rapidly spreading throughout the medium, whereas *B. coli* remained confined to the point of inoculation as usual. Of a great variety of media tried, I obtained the best results with an agar-gelatin containing ·5 per cent. agar and 5 per cent. gelatin, incubation taking place at 35° C.; but the only essential appears to be that the necessary relation between the stiffness of the medium and the incubating temperature shall be maintained. For this purpose it is necessary to be a little more than usually critical in its preparation. The following method gives satisfactory results:

Place 500 c.c. meat infusion in a beaker of about 1,500 c.c. capacity and weigh; heat over a naked flame until just boiling, then throw in 5 grammes agar cut up small, but not previously wetted, cover with a clock glass, and boil gently, placing the flame a little to one side of the bottom of the beaker. The agar will boil down little by little, and will be kept in rapid rotation so that it cannot stick and burn. Continue until the whole of the agar is disintegrated, which will occupy about two hours, occasionally adding boiling distilled water to replace loss. There will be no discoloration. When the operation is complete, make up to the original weight with boiling distilled water. Add 5 grammes peptone and 2·5 grammes salt, and render distinctly alkaline. Boil up again, place in boiling sterilizer, and allow to cool in it overnight. When cold, turn out the mass, cut off the deposit at bottom, remelt, and mix with an equal weight of 10 per cent. nutrient gelatin.

The agar-gelatin should be poured into dishes or flat-bottomed flasks to a depth of about 5 mm. and allowed to cool slowly, preferably in the sterilizer. In use the centre of the medium is touched with a platinum loop charged with the material to be examined, the flask or dish is enclosed in a much larger one in order to prevent condensation, and the whole is placed in an incubator kept at 35° C. for twenty-four hours. Pure cultures of typhoid so treated produce an opalescence occupying about

two-thirds of the medium; *B. coli* gives a flat plate somewhat thicker and moister than the usual form. If the inoculation is made with both organisms, either from separate cultures or from a mixed culture, we get a flat plate of *B. coli* in the centre, with an opalescent halo of pure typhoid. Plates of this medium, inoculated direct from typhoid stools, gave without difficulty the same pure culture of typhoid bacilli; and I anticipate this will become a valuable diagnostic test as easy of application, though not quite as rapid, as the serum test. It is best applied by putting two or three loops of stool into a little sterile broth, shaking and inoculating as described. Tap-water, also inoculated with a trace of a broth culture of typhoid, or typhoid and coli mixed, readily yielded pure cultures of ty hoid. I may point out that here is a legitimate application of the preliminary filtration; the concentrated particulate matter is just what is wanted for this test. I have abandoned this step, however, in favour of a separation of micro-organisms, and, indeed, all suspended matters by centrifugal action. I find that by the aid of a slight chemical precipitation a moderately pure water can be completely sterilized, and the micro-organisms collected in a small amount of sediment by whirling in a Leffmann-Beam machine. This apparatus, however, does not deal effectively with sewage or badly-polluted waters, and I am now engaged in perfecting this mode of concentration.

I was then in possession of a reliable means of effecting the much-desired separation, but thought it necessary to confirm on cultures from other sources, especially as it was becoming known that there were many varieties of *B. coli*, and it was even maintained that the typhoid bacillus was only one of these varieties endowed with exceptional virulence. I obtained, therefore, several specimens of typhoid and three of *B. coli* from bacteriological friends, besides preparing fresh typhoid from spleens and stools.

The typhoids were all practically identical, answered to all the classical tests, and I may say in two words that I have no doubt the typhoid bacillus is a distinct and definite species, not to be confused with anything I have ever found in water, sewage, or healthy fæces. It was quite otherwise with *B. coli*. The three new pure cultures consisted quite clearly of three distinct species, and amongst them was one that comported itself in agar-gelatin like typhoid. At the same time I was accumulating coli-like forms from waters and sewage, several of which behaved in the same way. In doubt as to the value of my test, I applied to Dr. Escherich, who, as the discoverer of *B. coli*, would be in the best position to settle its true characteristics, and he most kindly sent me pure cultures. The *B. coli* so obtained was not identical with any of the others, but resembled most nearly my original culture (obtained from fæces), and it behaved exactly as described in the agar-gelatin medium. I was therefore confirmed in the value of the test as regards typhoid on the one hand, and *B. coli* with a number of its near relations on the other.

I arrived at this stage rather more than two years ago, and my attention was then naturally directed to the study of those forms which behaved generally like *B. coli*, but which grew in agar-gelatin like typhoid. Unfortunately, as far as my experience goes, there is a similar antagonism between them and typhoid—at least in some cases—to that observed in broth cultures. Certain of these organisms occupy the medium to the exclusion of typhoid. If the opalescent growth consisted of both

organisms in equal or nearly equal proportions, of course the separation could easily be completed by plating out. But this does not appear to be the case, and my work here only revealed a greater depth of complication as regards the isolation of the typhoid bacillus. Still, I think it will be conceded that the satisfactory separation of the typhoid and coli bacilli is of sufficient interest to be worth recording, and was a necessary step in the demonstration of the presence of other forms which may mask the typhoid bacillus if present in water. But incidentally some considerations which appear to me to be of the gravest import in connection with the question of water-supply have forced themselves on my attention.

I have during the past three or four years collected a great number of coli-like organisms from natural waters and similar sources. Now, until lately it was the unscientific fashion to refer to bacilli which answered to some only of the usual tests for *B. coli* as "varieties." Thus, one variety did not coagulate milk, another did not form indol, and so on. Latterly, at the instance, I think, of Dr. Klein, all these have been quite rightly dissociated from *B. coli;* they are evidently distinct species, and so numerous that I have long since ceased to collect them for lack of space. But I have to carry the process of differentiation a step further. *B. coli* in the narrower sense is defined as a short oval or subcylindrical bacillus which grows rapidly on the surface of nutrient gelatin, forming a thin plate with irregular margin; it produces gas in glucose media, coagulates milk in two or three days at 37·5° C., and produces indol in broth culture. There are also some minor and less definite characters, such as paucity of flagella and feeble motility. Now, amongst the organisms isolated in my experiments, I have already found more than a dozen practically indistinguishable by means of the tests alluded to, but which I shall have little difficulty in convincing you are entirely distinct species. There are several features, such as morphological differences under rigidly constant conditions of culture, which I believe are truly specific, but which may not be so regarded by all observers. I shall therefore ignore them for the present, and confine myself to characteristics as to which there can be no such difference of opinion. The appended table (see next page) contains such an account of thirteen species, grouped so as to bring out the chief points of difference. There are one or two of the tests which require a word of explanation.

Touch-culture on Gelatin.—It is well recognised that in gelatin cultures of this class of bacillus the surface colonies only take at all a characteristic appearance; and this is modified by the amount of inoculating material, the length of time that elapses before the growing colony reaches the surface, the propinquity of neighbouring colonies, the temperature of incubation, and the age of the medium. In order to control these influences, I have adopted the following procedure, which I call a touch culture. A growth is lightly touched with the extreme point of a plain needle, which is then applied vertically and as lightly as possible to the surface of a freshly-poured 10 per cent. gelatin plate, and this is repeated until the charge is exhausted. The plates are then enclosed in a larger chamber, and incubated at 20° C. for four days. Very characteristic appearances are thus obtained, which are perfectly constant for the same organism. Typhoid is readily distinguished from all the coli-like forms by the slow rate of growth and the pattern of the expansion. Similarly, the forms exhibited may be divided into three classes according to their behaviour, and some

Designation.	Source.	Touch Culture, 4 days at 20° C.	Halo Test.	Serum Test.	Flagella (maximum number).	Distinctive Characters.
C_1	Fæces	Rather thick irregular expansions, with dentate margins. Diameter on fourth day not exceeding 10 mm.	–	+	5; short, and slightly wavy.	Very limited expansion in touch culture. Halo and serum tests in combination.
C_7	Water		+	+	8; long, wavy.	Most like C_8, but distinguished by absence of marked odour, character of halo, and by micro-examination of agar colonies (well-marked bacilli with threads).
C_{13}	Fæces		+	–	5; long, stout.	Most like C_8, C_9, and C_{10}, but distinguished by limited touch culture and character of flagella.
C_2	Pure culture	Thin expansions, with veined and pitted surface and indented margins. Diameter about 20 mm.	–	–	4; very regular wiry spirals of 6 to 8 turns.	Flagella quite characteristic; broth cultures have great tendency to clear rapidly.
C_4	Pure culture		–	–	1; slightly wavy.	All cultures extremely viscid. Flagella distinctive.
C_8	Water		+	+	5; long, wavy.	Halo culture characteristically thick, with abrupt margin. All cultures very repulsive urino-fæcal odour.
C_3	Pure culture	Very thin expansions, with variable surface and foliated margin. Diameter about 30 mm. Growth similar, though smaller, at 12° C., except C_6 and C_{10}, which do not expand, but form moist white elevations.	+	+ +	3; short.	Serum test. Flagella.
C_5	Pure culture (Escherich)		–	–	0	Distinguished from C_{12} by micro-examination of margin of impression preparation.
C_6	Water		+	–	1; stout, slightly wavy.	Touch culture at 12° C. Flagella.
C_9	Fæces		+	–	5; very wavy.	Agar growths at 20° C. So short as to look like cocci.
C_{10}	Water		+	–	8; long and wavy.	Touch culture at 12° C. Flagella.
C_{11}	Water		+	+	3; delicate.	Touch culture; quite characteristic "matt" surface; much more uniform than others, both in surface and margin, which is almost devoid of indentations.
C_{12}	Sewage		–	–	0	Most like C_5, but constant morphological differences.

individuals, notably C_1 and C_{11}, may be at once identified in this manner. Further, the colonies so formed make most excellent impression preparations, the marginal organisms in which in many cases present constant and distinctive morphological features.

Halo Culture.—This refers to the agar-gelatin culture already described. It divides the organisms into two well-defined groups, and furnishes a definite test for C_8.

Serum Test.—It is, I think, a new observation that several organisms react quite as powerfully with anti-typhoid serum as does the typhoid bacillus itself. As a test for typhoid bacilli, therefore, this process fails, though it does not of course follow that the converse "serum diagnosis" of typhoid is misleading. The mode of application is simple. To 5 c.c. of a twenty-four hours broth culture is added the minimum dose of serum found to give a distinct reaction with a typhoid culture; this is generally about ·25 c.c. C_3 gives a more immediate reaction than typhoid; C_1, C_7, C_8, and C_{11} behave very like the latter.

Flagella.—The number and character of these interesting appendages, commonly, though almost certainly erroneously, regarded as locomotive organs, furnish a useful means of distinction between typhoid and *B. coli*, and to a less degree between the members of the coli group. As long as the staining of flagella was a matter of considerable uncertainty this was not the case; but now that Van Ermengem's silver process makes it possible to get uniformly successful preparations, there is no difficulty in grouping these forms on this basis. Thus, one class will consist of those which exhibit no flagella (C_5 and C_{12}); these are more easily recognised by the complete absence of detached flagella, so conspicuous a feature in typhoid preparations. The second group will include those forms which possess one terminal, rather massive flagellum, bacilli on the point of dividing being sometimes provided with one at each end (C_4 and C_6). The third group embraces those furnished with a fringe of three to eight flagella. One form (C_2) is absolutely distinguished from all the rest by the character of its flagella. It is worth noting that it is much more difficult to distribute the coli-like forms through water than typhoid bacilli, and it is very necessary to be on one's guard against mistaking a mass of pauci-flagellate forms for one multi-flagellate organism. In carrying out this process, and, indeed, in making all cover-glass preparations, it is very advantageous to substitute fixing with formalin for heating; both fixation and subsequent staining are much improved.

Indol and Gas Formation.—These generic tests proved very uncertain in my hands, until I observed that it was absolutely necessary that the broth used should be made from very fresh meat, and that the latter should not be allowed to macerate in water before steaming. With media prepared in this way, there is no need of the addition of glucose in observing gas formation, and the indol reaction is very strong. A very pretty and reliable mode of applying the latter test is to use an agar culture, such as is prepared to demonstrate flagella. If a warm solution of nitrous acid, made by adding 1 part of pure sulphuric acid to 10 parts of 0·02 per cent. solution of potassium nitrite, be poured over such a culture, a pink coloration rapidly appears in the superficial layers.

Now, an examination of this table will, I think, make it quite clear that the

organisms referred to are fairly entitled to be considered distinct species. It should be remembered that most of them have been carried through dozens of generations, and still present the same distinctive features. Yet they all conform so exactly to the published description of *B. coli*, that probably no bacteriologist would hesitate to recognise them as typical colon bacilli; indeed, as already stated, several of them were presented to me as such. Nevertheless, the odds against the correctness of the diagnosis, even with our present limited experience, would be twelve to one.

In fact, the number of known species appears to be determined by the range of our discriminating tests, rather than by their actual limitation in Nature. These tests, too, have been collected and arranged with a view to the distinction between the typhoid bacillus and the group of which *B. coli* is the type, and were not intended primarily as a means of recognising this latter. The positive identification of *B. coli* is one of the most difficult tasks of bacteriology.

But this is more than a bit of systematic biology. We are accustomed to draw most important inferences from the discovery of *B. coli*. Take first the number of pathological conditions with which this organism is said to be associated. We are told repeatedly that it has been found in this, that, and the other morbid condition—in peritonitis especially. I read the other day that, after a cadaver had been roughly placed on the post-mortem table, a discharge took place from the external auditory meatus which proved to be a pure culture of *B. coli*. Apart from the singularity of finding a pure culture of anything under such conditions, there was nothing to show that the extremely delicate operation of identifying *B. coli* had been successfully carried out. And this is a fair sample of dozens of similar records.

But a more important matter to us as analysts is the significance of the presence of *B. coli* in drinking-water. It is pretty generally accepted that the normal habitat of *B. coli* is the large intestine, and that its presence in water in any quantity is a certain index of fæcal pollution. There are two assumptions involved in this view which will repay consideration. The first is that *B. coli* is a definite and readily-recognised species, so that there may be no doubt about its identity when met with. I think I have shown that *B. coli*, as generally understood, undoubtedly comprises at least a great many distinct species, that the positive recognition of the true *B. coli* is extremely difficult, not to say impossible, as yet, and that any record of its occurrence, to be placed beyond question, must be accompanied by much more convincing proofs of its identity than have been adduced in any instance hitherto published.

A second assumption is that *B. coli* does not occur in abundance in organic matters other than animal excreta. The mode in which this very dubious theory has developed is instructive. The bacillus was originally found by Escherich in the excrement of infants fed exclusively on mother's milk. Subsequently other investigators found an apparently identical organism in the intestine of man and other animals—a habitat that was soon extended to air, water, soil, and pretty much everything on the terrestrial globe. No proof of this identity beyond the simple characters given originally by Escherich was advanced, and the almost universal presence of the bacillus has been explained by the dissemination of excrement by natural agencies. It will be seen at once on what a slender thread the connection

between *B. coli* and animal excreta rests, and how untrustworthy is the inference so commonly drawn from its supposed discovery in natural waters. It has never been shown that any well-defined species is so invariably associated with excremental matter that its presence can, with any show of reason, be held to constitute a certain index of fæcal pollution. The true *B. coli*, so far as my experience goes, is not generally, if at all, to be found in the intestine, still less in sewage-polluted waters. And, indeed, the connection between *B. coli* and fæcal matter is not even now accepted in the complete and unreserved fashion which should be the case where such important issues are at stake. Let me refer you to one of our best practical handbooks—the manual written by Drs. Kanthack and Drysdale. If you turn to the directions given for obtaining *B. coli*, you will find the recommendation to add to sterile broth some minced fresh meat, and to incubate for twenty-four hours, when a mixture of organisms, including *B. coli*, will result. There is no mention of sewage, fæces, or similar material.

No; when the history of *B. coli* comes to be written, it will be found to be altogether parallel to that of *B. termo*. In both cases a number of saprophytic organisms possessing a superficial resemblance have been confused together; our processes have for some time been capable of distinguishing between some of the forms previously collected together under the name *B. termo*, which undoubtedly included the several species now massed together as *B. coli;* we are hardly yet in a position to deal equally definitely with the latter, and until we are able to single out a form specifically associated with fæcal matter, and at least as easily recognisable as the tubercle or diphtheria bacillus, we shall do well to avoid such expressions as contain index of fæcal pollution.

It may, of course, be argued with some force that the precise identification of species is a matter of small importance, and that the presence of organisms whose function is to break up organic filth is objectionable in a drinking-water, in so far as it is evidence of the existence of that filth. With this one is not disposed to quarrel, but it is no answer to my criticism, which is directed against the inference that this filth is derived from the intestine of an animal because the associated organisms necessarily originated in this locality. When an assertion of this kind is made, it is time to ask for some evidence in support. The sanitary significance of the minute quantity of pabulum necessary for the vigorous life of these organisms will vary enormously, according to its supposed origin; and at present there is no satisfactory evidence that any of the organisms grouped under the general term *B. coli* afford by their presence specific indication of contamination with fæcal matter.

But lately a further refinement has been made in connection with river-water supplies to large towns, especially the Metropolis. It is said that not only is *B. coli* found in unfiltered river-water, but that it passes the sand filters, as is proved by the discovery of the same organism in the filtered water. I would ask again, How has the identity of *B. coli* been determined? is there any reasonable proof that some of these organisms, which may certainly be found in water completely innocent of admixture with sewage, have not been mistaken for *B. coli?* how is it possible to establish the identity of the organisms in the filtered and unfiltered water, if the only available tests are insufficient to discriminate between not two only, but a dozen or more distinct species.

I have merely touched upon these matters, wishing to hear by way of discussion what are the views of those present; but I would remind you that the tendency to hastily assert the identity of similar organisms has over and over again checked the progress of bacteriology, though in no former instance, perhaps, has the confusion carried with it such important consequences.

Bacilli which grow in broth at 37·5° C., rendering it turbid, and producing indol in twenty-four to forty-eight hours, grow vigorously in phenolated media, coagulate milk in two to three days, produce gas in media containing sugar, do not liquefy gelatin, but develop on the surface into a thin, flat expansion, with irregular margin, and are indistinguishable by ordinary plate, stroke, or stab culture.

Explanation of the accompanying Plate.

Discussion.

The President said that, in addition to members of the Society of Public Analysts who had worked on this subject, the meeting was fortunate in having among its visitors several professional bacteriologists, among whom was Dr. Pakes, whom the Society had met before upon a similar occasion, and he would call upon Dr. Pakes to be kind enough to contribute something to the discussion.

Dr. Pakes said he would like to begin by saying with what a large amount of interest he had listened to this paper. He really felt envious of the energy which Mr. Stoddart must have possessed to be able to get through the quantity of work necessary in such an investigation. It seemed rather puerile to commence carping upon details, when such an important matter was at stake, but there were one or two points on which he would like to ask questions of Mr. Stoddart.

In the first place, Mr. Stoddart had said that if typhoid and colon bacilli were planted in broth, a mixed culture was obtained, from which it was possible to separate the typhoid bacilli. His own experience was that, if coli and typhoid were planted together, the coli was obtained at the expense of the typhoid. He had made a large number of experiments in this connection, and had come to the conclusion that, at whatever temperature the organisms were planted, absolutely pure cultures of coli were obtained, it being impossible to recover the typhoid. He had grown at all temperatures, and examined after all intervals of time, and had never been able to recover the typhoid bacillus from a mixed culture of colon and typhoid, when the typhoid bacilli were inoculated in an equal or less quantity than the colon bacilli. It could, however, be recovered when it was in the proportion of, say, three to one.

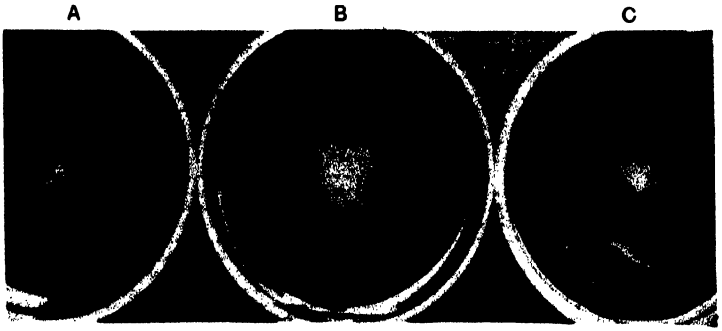

Fig. 1.

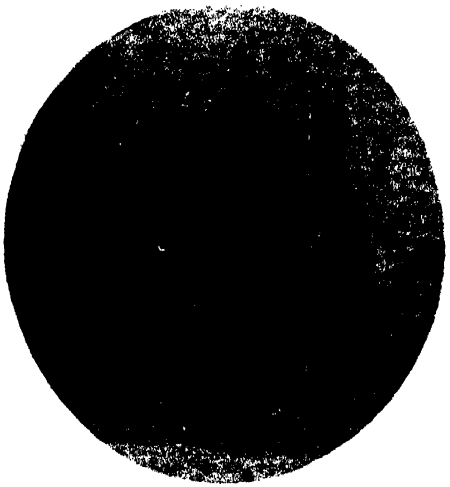

Fig. 2.

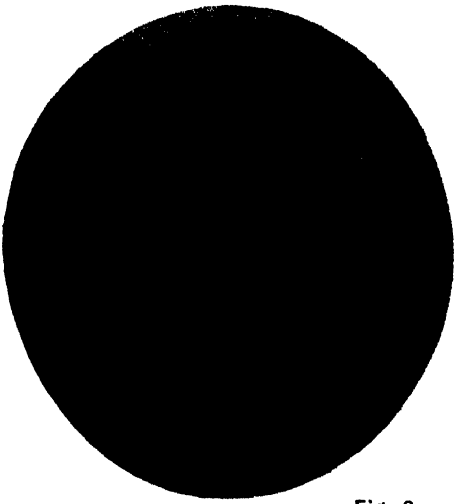

Fig. 3.

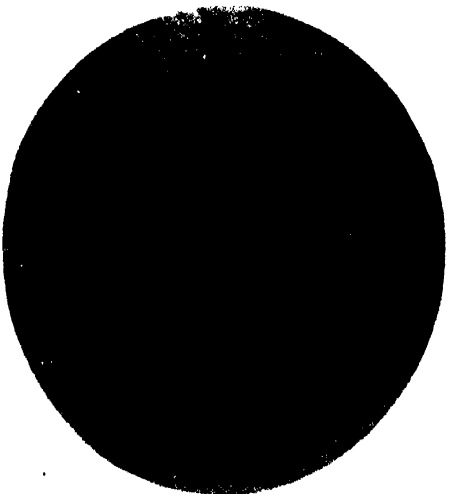

Fig. 4.

Mr. Stoddart had referred to a number of cultures, which he said conformed to the dicta laid down by Escherich as to what the colon bacillus was, but which he (Mr. Stoddart) believed to be distinct from true coli. The speaker desired to know what Mr. Stoddart himself would lay down as the reactions of the true colon bacillus, since all his cultures gave the reactions which Escherich described as pathognomonic of the colon bacillus.

There was one very important factor which Mr. Stoddart had absolutely omitted to mention, viz., the amount of acid produced. It was certainly a reaction which had only been systematically made use of during the last two or three years, but, as Mr. Stoddart would know, the acidity produced by the typhoid bacillus was extremely small in comparison with that produced by most of the organisms that were looked upon as varieties of the colon bacillus.

He (Dr. Pakes) had eleven different cultivations of the colon bacillus, which he had obtained from different sources, actually growing and living. These also conformed to the description of the true bacillus coli; that was to say, they produced the characteristic reactions in broth, with the formation of indol in milk, on gelatine, on agar, and on gelatin agar.

He did not know whence he got the idea of using the last-mentioned medium, but he had employed it for some time. He noticed that Mr. Stoddart had said that 5 + ·5 per cent. gelatin agar would stand a temperature of 35° C. He (Dr. Pakes) had never worked at 35°, but always at 37° C., and he had found that the 5 per cent. medium would not remain sufficiently stiff to enable it to be used at 37°. He could fully bear out what Mr. Stoddart had said with regard to the appearances of the colonies of the two organisms on this medium. Those of the colon bacillus were very much more heaped up, and spread very much less in the same time, than those of typhoid.

With regard to the serum test, as was well known, this test for the diagnosis of typhoid fever was very much to the fore, and during the last three months he had had several opportunities of applying it. It seemed to him that there were some fallacies in the test as applied by Mr. Stoddart. Given the serum of a patient undoubtedly suffering from typhoid, and given two cultures of the typhoid bacillus (which was far more easy to identify than the colon bacillus), one extremely virulent and the other practically non-virulent, it would be found that the former was acted upon better than the latter. Why this should be he could not exactly make out, but it would seem that there was a difference in the action of the bacillus according as it was virulent or not.

He had not heard a word on the subject of the pathogenicity of these different varieties of coli. He had obtained upon different occasions organisms which he certainly thought to be coli, but which, when inoculated into susceptible animals like guinea-pigs, all proved to be non-pathogenic. It would seem, therefore, either that a virulent form of coli existed, or that the organisms in question were not what they were taken to be.

With regard to the different appearances presented by the organisms referred to by Mr. Stoddart, there seemed to be no doubt that certain organisms did vary very largely, in proportion to their virulence, and according to their surroundings. For

instance, the anthrax bacillus, when grown under certain conditions, lost its power of sporulating. Such phenomena were simply dependent upon environment, and it seemed to him possible, if he might suppose for a moment that these organisms did belong to the same species, that such small differences as existed between some of them might have been developed simply by different environment.

These were the points which had struck him in connection with the paper. No doubt Mr. Stoddart had a good explanation to offer for the differences of opinion which he (Dr. Pakes) had given.

He felt that he must express his indebtedness to Mr. Stoddart for a large amount of knowledge gained from the paper, and he desired to put forward the small points on which he differed from Mr. Stoddart, not in any spirit of carping, but with all due deference.

Mr. JOSEPH LUNT, B.Sc., asked whether Mr. Stoddart had succeeded in actually obtaining the typhoid bacillus from naturally polluted water suspected of having given rise to the disease.

He thought Mr. Stoddart had demonstrated that his method, which was a very ingenious and beautiful one, afforded a ready means of separating the typhoid and colon bacilli from artificially mixed pure cultures, and also of obtaining the typhoid organism from typhoid stools, which was a great step in advance; but unfortunately, as Mr. Stoddart showed, there were other organisms which resembled either the typhoid bacillus or *Bacillus coli*, which behaved in the same way as typhoid by his method. It was unfortunate that the typhoid organism could not be obtained absolutely alone. If this could be done, an invaluable advance would have been made. He did not quite understand how Mr. Stoddart distinguished between many of the organisms of the coli group shown in his table. The only differences between some of them seemed to be in the number of their flagella, and it was his experience that just such variations were often obtained in the various individual bacilli in a pure cultivation, so that he thought it would be very unwise to draw any positive deduction from this characteristic alone.

He had been in the habit himself of using such touch cultures as Mr. Stoddart had referred to, and had found that the diameter of the colonies in these cultures was very variable. It might very well happen that one touch would give rise to a colony 20 millimetres in diameter, while another from the same variety would grow only 10 millimetres, owing to the variable amount of sowing material used, and also owing to variations in their vitality. He could not, therefore, agree with Mr. Stoddart that the differences shown by these cultures were very essential ones, unless other characteristics confirmed the indications given by the diameter of the colonies at a certain age.

He therefore did not consider that Mr. Stoddart had fully demonstrated specific differences between all the coli organisms he had regarded as distinct from one another.

He quite agreed that it was rather a hopeless task to find typhoid bacilli when mixed with *B. coli* in large quantity by Parietti's method, in which carbolized media were used, and hoped Mr. Stoddart's method would receive the attention it well deserved.

Mr. C. G. Moor said that he had always been impressed with the necessity for not working upon a tenth or hundredth part of a cubic centimetre, and as the organisms might be injured by the method of concentration (filtering the water through a Pasteur or Berkefeld filter), he had tried using glass plates about 2 feet across, which enabled a much larger quantity to be worked upon.

He had obtained better results with Elsner's method than with the other published methods, and if any likely colonies were taken from Elsner's medium and put into milk, those that caused curdling could be rejected as certainly not being typhoid; there would not then be such a large number of colonies that it would be impossible to deal with them.

When agar was soaked overnight it dissolved in hot broth in about half an hour.

When organisms were cultured through several generations, they changed considerably in size, so that the size of the organisms could not be regarded as affording very conclusive evidence. The number of flagella was also liable to alteration. It was well known, for instance, that the number of flagella possessed by the cholera bacillus was reduced, after prolonged subculture, from three or four to one or two only.

Dr. Pakes said he would like to mention that the substitution of powdered agar for the ordinary agar rendered the making of this medium extremely simple. They had used it in the laboratory at Guy's Hospital for the last two and a half years, and would certainly not like to go back to the old kind.

Mr. Stoddart said he thought he had been treated very kindly in the discussion, most of the observations having been rather in his support than otherwise.

With reference to the remark of Dr. Pakes that a mixed growth of typhoid and coli, unless the typhoid was largely in excess to start with, would result in the suppression of the typhoid, he thought that, with a slight verbal change, it would be found that this was exactly what he himself had said, which was to the effect that when any of several of the bacilli referred to in the paper, and which would commonly be called colon bacilli, were grown in broth with typhoid, the latter was more or less completely suppressed, and could not be found by subsequent plate culture. The organisms which interfered in this way were generally those which behaved like typhoid in halo culture.

This, however, was not the case with other coli-like forms, or with the true *B. coli* itself, as received from Dr. Escherich. When typhoid was grown simultaneously with the last, there was no difficulty in recovering it by the halo culture.

He had never made any exact determinations of acidity with a view to distinction. It did not seem to him that a quantitative determination would confer any additional powers of discrimination, nor had he been aware that it was made use of in discriminating between the various members of this group of organisms. It was, however, a very interesting point, and he would certainly try if it would throw any light on the subject.

With regard to the matter of temperature, he could only say that he had made the medium exactly in the way he had described, and had kept the incubator at 35° C. The medium did not melt at that temperature, though it became so soft as to

shift if the plate was moved. It was necessary that it should be as soft as this in order to get the distinctive growth.

Those experiments on the pathogenicity of organisms which seemed so easy to make in London were practically out of the power of persons living in the provinces, where there was a great deal of opposition to anything in the nature of experiments on living animals, and this was the case in Bristol probably more than anywhere else. Any bacteriological investigation made in Bristol must necessarily be defective for this reason. He could not help this, but to attempt to make such experiments would be almost to risk one's life He admitted that it was a very grave defect in his paper, but he did not think it ought to altogether prevent his investigating this subject.

As to the effects of different surroundings, it was perfectly true that the same organism grown under widely different circumstances would change very considerably in its behaviour, but he hardly thought that this would apply to the present cases.

These thirteen organisms were obtained from different sources. C_{11} was from a water that nobody could complain of, either from an inspection of its source or from its chemical analysis. Some of the others were from fæcal matter. Nos. 2, 3, 4, and 5 were all given to him in pure culture as typical colon bacilli; but all had been carried through very numerous generations, in some cases for years, and yet they maintained the same distinctions.

The numbers of flagella given in the table represented the maximum numbers observable in a great many preparations. He did not mean to say that the difference between, say, 5 and 8 flagella was sufficient for positive discrimination, but, broadly speaking, he could draw a definite distinction between an organism which with some difficulty gave a single flagellum and another organism which showed an abundance of flagella.

The use of large dishes appeared to be an admirable modification. He had never himself adopted it, but it seemed to him a very proper modification of the plate process. However, with the method described in the paper, concentration to a small bulk was of course an advantage.

As to the practical suggestions which had been offered for obtaining good cultivation media, he could only express his gratitude for these, and say that he would certainly take the first opportunity he could of putting them into practice.

The PRESIDENT, in asking the meeting to accord its hearty thanks to Mr. Stoddart, said that no doubt all those present would like to see the preparations which Mr. Stoddart had kindly brought up. They were indebted to Mr. Ling and to Messrs. Watson for supplying several microscopes with excellent lenses; and with the aid of these Mr. Stoddart would have some demonstrations to make for those who would like to see them. He would also ask the meeting to return its thanks to the visitors for their contributions to the discussion.

FOOD AND DRUGS ANALYSIS.

The Determination of Aloin in Aloes. G. L. Schafer. (*Pharm. Zeit.*, 1897, 95; through *Jour. Pharm. Chim.*, 1897, 296.)—The method is based on the fact that aloin in ammoniacal solution forms compounds with the alkaline earths, which are but little soluble, and from which the aloin can be recovered on treatment with an acid.

Fifty grammes of aloes are treated with 300 c.c. of boiling water containing a few drops of hydrochloric acid, and when cold the solution is separated from the resin. Fifty c.c. of 20 per cent. ammonia and 15 grammes of calcium chloride in 30 c.c. of water are then added, and the whole well shaken. After fifteen minutes the precipitate is separated, and after being pressed is triturated in a mortar with a slight excess of hydrochloric acid. The aloin and calcium chloride are dissolved in as little boiling water as possible, and filtered. On cooling the aloin separates in crystals.

The amount of aloin found by the author in different varieties of commercial aloes varied between 15 and 30 per cent. C. A. M.

ORGANIC ANALYSIS.

Determination of Fat in Oil-cakes. A. Bilteryst. (*Bull. de l'Ass. belge*, 1897, x., 406-412.)—In this paper it is shown that carbon tetrachloride may be advantageously substituted for ether in extracting the fat from oil-cakes. The extraction may either be made in a Soxhlet's tube in the ordinary manner, or the pulverized cake may be extracted in the cold for twenty-four hours, and the extract determined in an aliquot portion of the solvent. In the former case preliminary drying of the substance at 100° C. is unnecessary, since carbon tetrachloride is not miscible with water; the risk of the solvent taking fire is obviated, and the extraction requires less time.

For the cold digestion, 20 grammes of the cake are mixed with 100 c.c. of carbon tetrachloride measured at 15° C., and left for twenty-four hours, an occasional shake being given. Fifty c.c. of the solution are filtered, evaporated on the water-bath, and the residue dried to constant weight. To obtain the amount in 10 grammes of the oil-cake, a correction is necessary for the volume occupied by the fat. This is made by dissolving the residue in 50 c.c. of carbon tetrachloride, noting the increase in volume, and calculating the result by proportion.

The following examples are taken from a long table:

	Extraction with Ether. Fat per cent.	Extraction with CCl_4 Hot. Fat per cent.	Extraction with CCl_4 Cold. Fat per cent.
Oil-cake (earth-nut)	7·94	7·95	7·92
,, ,, ...	9·07	9·10	9·12
,, (colza)...	10·45	10·40	10·43
,, (sesame)	14·80	14·80	14·75

C. A. M.

Examination of Beeswax. **R. Henriques.** (*Zeit. für öffent. Chemie*, iii., 66.)—In the preceding number of the *Zeit. für öffent. Chemie*, Woy drew attention to the difficulty of saponifying waxes by boiling with alcoholic $\frac{N}{2}$ solution, owing to the saponifiable portion being protected from the action of the alkali by the portion not saponifiable.

The author had already pointed out this difficulty in his paper on cold saponification (*Zeit. für angew. Chemie*, 1896, 221). He specially recommended his method of cold saponification as suitable in the case of beeswax, since the difficulty referred to is entirely obviated by the wax being dissolved in benzene prior to the addition of the alkali. Moreover, by this method saponification is complete at the ordinary temperature of the room, and therefore all danger of alteration in the volumetric solution is avoided. The author has had many opportunities of proving the accuracy of the method when applied to beeswax, both pure and adulterated, and he believes it would prove the most convenient method in many other cases, as, for instance, for wool-fat and resins. (See also ANALYST, vol. xxi., pp. 67 and 192.) H. H. B. S.

Adulterated Japan Wax. **C. H. La Wall.** (*Am. Journ. Pharm.*, 1897, lxix., 18-21.)—It is stated by the author that Japan wax is now being extensively adulterated in America with starchy material, to the extent of from 20 to 25 per cent. This was first detected in October, and the admixture has, so far as is known, always been made after the importation.

The appearance of the adulterated product is different from that of the genuine wax, being in most cases free from the network of cracks usually noticed on the surface of Japan wax. The presence of starch is readily detected by fracturing a cake and testing the freshly-exposed surface with iodine. The averages of the constants of four adulterated samples were: specific gravity, 1·0653; melting-point, 52° C.; saponification number, 173·28. From pure samples examined at the same time the figures were: specific gravity, 0·980; melting-point, 54° C.; saponification number, 220·98. The amount of foreign matter indicated by the lowering of the saponification number was calculated to be 21·24 per cent. The starch was also directly estimated by extracting the wax with chloroform, and washing the residual starch with ether and drying it at 100°. The quantity thus found was 23·42 per cent. The nature of the starch employed was not uniform. Under the microscope it was unmistakably identified as corn starch in one case, but in others there was some doubt as to its identity. C. A. M.

On the Chemical Examination of Cacao Butter. **F. Filsinger.** (*Zeit. für öffent. Chemie*, iii., 34.)—Cacao butter is found adulterated with cocoa-nut-oil and the surrogate fat which is prepared from it, with fine preparations of tallow, and with fatty oils principally sesame-oil. Paraffin and marrow-fat are no longer used for the purpose. The following tests, in addition to those of taste and smell, may be applied:

1. The iodine number.
2. The saponification number.
3. The acid number.
4. The melting-point.

Eventually, also, the refraction and the ether and ether-alcohol tests of Bjorklund and Filsinger. The iodine number, without doubt, throws the most light upon the question of adulteration. The number varies from 33·4 to 37·5. The addition of cocoa-nut-oil or its preparations (iodine number 4 to 8), or of preparations of tallow and sesame-oil (iodine numbers 40 to 45 and 108 to 110), respectively lower or raise the iodine number.

The saponification numbers of cacao butter and of cocoa-nut-oil are 195 and 250 respectively. It has not long been known that the acid number may rise as high as 40° to 50° Burstyn. When, however, this is the case, the iodine number is found to rise with it.

It is seldom the case that striking alterations of the melting-point arise through the admixture of foreign fats; even sesame-oil, in quantities usually added, occasions but a slight reduction. The melting-point of pure cacao butter varies from 32·0° to 33·6°. Information regarding refraction is as yet incomplete. Observations made so far at 35° C. give 50.

The purely empirical tests with ether and ether-alcohol, which were formerly relied upon, have now given place to more exact scientific methods. They are, however, still useful at times, as corroborative evidence in doubtful cases.

H. H. B. S.

Detection of Cholesterin in Fats. A. Forster and R. Riechelmann. (*Zeit. für öffent. Chemie*, iii., 10.)—Salowsky's method for the separation of cholesterin from fats has several drawbacks. It requires a considerable length of time for its execution; it takes a comparatively large quantity of ether (500 c.c. for 10 grammes of fat); the separation of the fluids is slow and often imperfect, and the saponification never complete.

By the method of Kossel and Obermüller, the separation of the soap is slow and incomplete, and the ethereal solution yields on cooling a crystallizable oil capable of further saponification.

The authors recommend the following process: 50 grammes of fat are twice boiled for about five minutes with 75 c.c. of alcohol of 95 to 96 per cent. in a flask with a reflux condenser attached, the flask meanwhile being well shaken. The alcohol is then cooled, to allow of the solidification of the fat, which is filtered off. The filtrate is mixed with 15 c.c. of a 50 per cent. soda solution, and boiled on the water-bath in a flask, with a condensation-tube attached, until about one-fourth of the alcohol has evaporated. The fluid is then poured into a porcelain basin, evaporated nearly to dryness, and the residue transferred to a shaking cylinder and shaken up with ether. The ethereal solution is evaporated to dryness, the residue treated with a little ether, filtered, evaporated, and the residue recrystallized from 95 per cent. alcohol.

H. H. B. S.

The Caffeine Compound in Kola. J. W. T. Knox and A. B. Prescott. (*Jour. Amer. Chem. Soc.*, 1897, xix., 63-90.)—In the authors' opinion none of the methods for the assay of kola have proved satisfactory, and the discrepancies in various analyses are to be attributed (1) to incomplete liberation of the alkaloids from their combination, and (2) to the caffeine being weighed in a state of greater or less purity, according to the method employed.

They consider that Gomberg's volumetric process of estimating caffeine (ANALYST, xxi., 193) is far more reliable than gravimetric methods in the analyses of kola, and in the following manner have obtained uniform and concordant results:

Preparation of Sample.—A sufficient quantity of the fresh sample is cut into very thin slices, which are allowed to fall into boiling alcohol, and after a few minutes' boiling removed and allowed to dry spontaneously on glass plates. The alcoholic solution is distilled to a syrup under reduced pressure (to avoid decomposition of the caffeine compound) and poured over the drying slices. When dry the drug is powdered in a mortar and preserved in stoppered bottles. As thus prepared the powder correctly represents the fresh seed without the water, and possibly a trifle of the volatile oil.

Free Alkaloids.—Five grammes of the powder are extracted for six hours with chloroform. To the residue, after evaporation of the chloroform, 30 c.c. of 1 per cent. hydrochloric acid are added, the liquid filtered to remove fat, and the filter washed with hot water. The united filtrate and washings (about 75 c.c.) are concentrated to 10-15 c.c., transferred to a graduated cylinder, and made up to 30 c.c. Thirty c.c. of standard Wagner's solution (1 c.c. = 0·00485 caffeine) are then run in from a burette, and the cylinder is well shaken. After standing for about five minutes the liquid is filtered through asbestos, an aliquot portion titrated with standard thiosulphate, and the amount of iodine absorbed by the alkaloids calculated into caffeine.

Combined Alkaloids.—The drug, after complete extraction with chloroform, is again extracted with 90 per cent. alcohol, two or three hours being usually sufficient. This alcoholic extract may then either be evaporated in a weighed basin, and the nitrogen contained in a small amount determined by combustion and calculated into caffeine, or to the hot alcoholic solution an excess of freshly-precipitated lead hydroxide may be added, the whole digested on the water-bath until the supernatant liquid is colorless, then mixed with sand, evaporated to dryness, the residue extracted with chloroform, and the caffeine determined volumetrically as before.

The following table gives the results obtained by this method of assay:

Sample.	Fresh Kola.				Dried Kola.		
	Moisture per cent.	Free Alkaloids per cent.	Combined Alkaloids per cent.	Total.	Free Alkaloids per cent.	Combined Alkaloids per cent.	Total.
No. 1. Dried kola, mixed—I. ...	6·16	—	—	—	1·859	1·783	3·642
,, ,, II. ...	—	—	—	—	1·828	1·836	3·664
Average	—	—	—	—	1·843	1·809	3·652
No. 2. Fresh kola, red and white seeds. Average ...	53·9	0·534	0·884	1·418	1·158	1·922	3·080
No. 3. Fresh kola, red and white seeds, very mouldy. Average	53·9	0·569	0·854	1·423	1·235	1·854	3·089
No. 4. Fresh kola, white seeds. Average	51·2	0·578	1·018	1·596	1·186	2·085	3·271
No. 5. Fresh kola, red seeds. Average	57·3	0·478	0·693	1·171	1·120	1·625	2·745

The method of Dohme and Engelhardt (*Am. Drugg.*, 1896, 12), which consists in boiling the dried and powdered drug for two hours in 30 per cent. alcohol, evaporating with sand and magnesia, extracting with chloroform, and weighing the dried residue, does not give reliable results. Thus, No. 1 in the preceding table when thus assayed yielded only (1) 2·04 and (2) 1·93 per cent. of caffeine, and even this, when titrated with Wagner's solution, was found to be not pure. But the principal source of error is shown to be owing to the fact that 30 per cent. alcohol does not completely remove the caffeine from its combination.

The Glucoside of Kola.—It is generally stated that kola contains a glucoside, *kolanin*, which is readily decomposable by heat, moisture, dilute acids, the ferment of kola, and by diastase, and which yields on decomposition caffeine, glucose, and ikola-red. But the authors consider that it is highly probable that this substance is really a mixture of tannates of caffeine and theobromine. They have prepared an artificial tannate of caffeine which closely corresponds both in ultimate composition and in chemical and physical characteristics with the natural kolanin.

Experiments with diastase and the kola ferment showed that any liberation of caffeine which occurred was due to the action of moisture and heat. Moreover, sterilization, although checking the formation of the coloured body, kola-red, did not interfere with the liberation of the alkaloids. Hence, the authors conclude that there is no evidence to show that kola-red and caffeine are joint products of the one hydrolysis of a glucoside, though such has been the conclusion of previous investigators.

Estimation of Theobromine.—The method of Kunze (ANALYST, xix., 94), with slight modifications, gives very satisfactory results. The ratio of theobromine to caffeine is fairly constant, and in a typical case the amount found in the free alkaloids was 1·48 per cent., and in the combined alkaloids 1·51 per cent.

Free Tannin.—For this estimation the authors employed a modification of the process given by Allen (*Comm. Organ. Anal.*, iii., part i., 76). The drug was exhausted with 95 per cent. alcohol, and the solution distilled *in vacuo* to a syrup, and then washed with water. The insoluble matter was removed and the clear solution fractionally precipitated with lead acetate (or hydroxide), the first and last portions of lead tannate being rejected. The lead tannate was well washed, suspended in alcohol, and decomposed with sulphuretted hydrogen. After filtration the alcoholic solution of tannin was distilled *in vacuo* to a syrupy consistence, and the evaporation completed in a vacuum desiccator over sulphuric acid. The tannin thus obtained was light red to reddish-brown, and behaved as other tannins do towards iron salts, gelatin, alkaloids, etc. It was a glucosidal body, yielding on hydrolysis with mineral acids glucose and a dark brown substance insoluble in water or alcohol, and containing carbon 69·20 per cent. and hydrogen 6·70 per cent.

Combined Tannin.—The tannin, in combination with the caffeine in kola, was separated by means of lead hydroxide. It agreed in appearance, composition, and properties with the free tannin, being also a glucosidal substance.

See also abstracts on kola, ANALYST, xx., 42, and xxi., 265 and 292.

C. A. M.

Valuation of Raw and Manufactured Caoutchouc. R. Henriques. (*Zeit. für öffent. Chemie*, iii., 37.)—Raw caoutchouc contains water; inorganic substances, as sand, stone, clay, etc.; organic impurities, accidentally introduced, as leaves and twigs; gum resins from other plants added by way of adulteration; and the so-called caoutchouc resin, which is distinguished from the true caoutchouc substance by its ready solubility in ethylic and methylic alcohol and in acetone. That which remains after the separation of these constituents is the pure caoutchouc substance, upon which the value of the commercial product depends.

The analysis of raw caoutchouc is carried out as follows: A weighed portion (50 to 100 grammes) is macerated in water in a small roller apparatus—similar to the kneading and washing machine used in indiarubber works—by which the mechanical impurities are eliminated. The resulting rubber is dried at 80° to 90°, and weighed. If a proper macerating apparatus is not at the operator's disposal, the mechanical impurities may be got rid of by the aid of water and a pair of scissors. Five to 10 grammes of the washed and dried rubber are then digested for two to three hours in acetone in a Soxhlet apparatus, to effect the extraction of the caoutchouc resin, the residue being then quickly dried and weighed. The determination of the ash completes the analysis, the percentage of true caoutchouc being obtained by difference.

The principal constituents of manufactured rubber are:

1. Added substances of the most divers description, such as lead oxide, heavy spar, gypsum, zinc oxide and carbonate, chalk, potash, magnesia and magnesium carbonate, golden antimony sulphide, ferric oxide, kieselguhr, asbestos, powdered glass, pumice-stone, etc.
2. Caoutchouc resin, soluble in alkalies.
3. Caoutchouc surrogate, asphalt and gum resins.
4. Free sulphur.
5. Caoutchouc resin in the insoluble form.
6. Combined sulphur, as vulcanite.
7. True caoutchouc substance.

The following is the procedure for the analysis of manufactured caoutchouc: The sample is reduced to a fine powder by the aid of a sharp file. Five grammes are then boiled for from three to four hours in a 3 per cent. to 4 per cent. alcoholic solution of sodium hydrate, which effects the solution of the free sulphur, resin, caoutchouc surrogate and the soluble caoutchouc resin, in addition to which, of course, many inorganic constituents may be attacked and partly dissolved. The solution is then filtered while still boiling, and washed with boiling alcohol. If the presence of asphalt be suspected, the residue is treated with cold nitrobenzol; otherwise this operation may be omitted. The residue is then washed into a beaker and boiled several times, first with water and afterwards with hydrochloric acid, the washings each time being decanted through the same filter. The residue is then all brought on to the filter, washed with hot water, pressed, dried at 80° to 100°, and weighed. The drying must not be continued longer than necessary, as the dry caoutchouc gradually takes up oxygen. The residue now contains the caoutchouc substance, the combined sulphur, insoluble inorganic substances, such as silicates, barium sulphate, etc., a very trifling quantity of the caoutchouc resin, and a little

carbonaceous matter added for coloring purposes. If the ash and the sulphur be now determined and their amounts deducted from the residue, the remainder will be the true caoutchouc substance.

H. H. B. S.

INORGANIC ANALYSIS.

The Application of Nitroso-β-Naphthol to Inorganic Analysis. R. Burgass. (*Zeit. angew. Chem.*, 1896, 596-601.)—When in solution as chlorides or sulphates, iron and cobalt can be precipitated together by an acetic acid solution of nitroso-β-naphthol, the oxides weighed after ignition, then dissolved in hydrochloric acid, and the iron determined in the usual manner. The nitroso-naphthol is dissolved in 50 per cent. acetic acid, and in making the determination 10 to 20 c.c. of acetic acid must also be added to the solution of the metals, which has been previously heated with 2 or 3 c.c. of hydrochloric acid and allowed to cool to 95° C. The precipitate is washed with hot water (not too much) containing a little hydrochloric acid, and then with water alone, and ignited without previous drying in a capacious platinum crucible.

Copper is also precipitated quantitatively, while the following metals remain in solution: mercury, nickel, chromium, manganese, lead, zinc, aluminium, cadmium, magnesium, calcium, beryllium, antimony, and arsenic.

Silver, tin, and bismuth are only partially precipitated, and must therefore be removed before adding the nitroso-naphthol. In order to prevent any antimony being precipitated as oxychloride, 10 to 15 c.c. of a solution of tartaric acid (1 : 5) should be added. The antimony cannot be determined directly as sulphide in the filtrate, since the latter always contains some nitroso-naphthol. The sulphide should therefore be treated with fuming nitric acid, and the antimony determined as oxide by igniting in a porcelain crucible.

Similarly, arsenic cannot be directly determined in the filtrate, which should be oxidized with potassium chlorate and hydrochloric acid, and the arsenic then estimated as magnesium pyro-arseriate.

In the case of iron, phosphoric acid is simultaneously precipitated, sometimes almost quantitatively, and hence interferes with the determination; but it does not affect the estimation of cobalt or copper. The determination of all three is vitiated by the presence of tungstic or molybdic acids.

In order to obtain correct results by this method, it is necessary to take not more than 0·3 gramme of the substance to be precipitated, and to have a sufficient quantity of free acetic acid present. C. A. M.

Formaldehyde as a Reducing Agent in Analysis. B. Grützner. (*Arch. Pharm.*, 1896, ccxxxiv., 634; through *Chem. Zeit. Rep.*, 1896, 314.)—On acidifying a solution of potassium chlorate containing silver nitrate and formalin with nitric acid, the chlorine separates quantitatively as silver chloride, especially on warming; and the reaction may be employed gravimetrically or volumetrically for estimating either the formalin or chloric acid. Mixtures of chlorides and chlorates may be titrated

with silver to give the chloride, and then reduced with formalin and nitric acid and again titrated to obtain the chlorate. Bromates behave in a similar manner, but it is necessary to heat the liquid for two or three hours on the water-bath. Periodic and perchloric acids are only slightly reduced, and iodic acid not at all.

F. H. L.

Preparation of Pure Oxalic Acid. R. Riechelman. (*Zeit. für öffentl. Chemie*, iii., 13.)—For the preparation of chemically-pure oxalic acid for use in standardizing volumetric solutions, it is recommended to recrystallize the commercial product, first from ether and afterwards from water. For expediting the solution of the oxalic acid in ether, the use of Soxhlet's apparatus is advised. H. H. B. S.

On the Constancy of Standard Solutions of Permanganate when Protected with a Layer of Vaseline Oil. Meineke and Schroeder. (*Zeit. für öffentl. Chemie*, iii., 5.)—Although solutions of permanganate keep well when prepared from the pure crystallized salt, yet when stored in large vessels with syphon connections to burettes there is always a danger of alteration through loss of water by evaporation. As a protection against this, the authors propose a layer of vaseline oil floated upon the surface of the solution, and they have carried out a series of experiments to ascertain if it exercised any reducing effect upon permanganate.

Experiments were made with the oil in its natural state, as well as after purification by treatment with permanganate in alkaline, neutral, and acid solutions.

The authors conclude that while the results obtained with the purified oil do not justify the trouble bestowed upon it, the reducing action of the oil in its natural state is so very slight that it may well be disregarded. H. H. B. S.

Detection and Estimation of Perchlorate in Nitrate of Soda. 1. Erck (*Chem. Zeit.*, 1897, xxi., 10); 2. F. Winteler (*loc. cit.*, p. 75.)—It has recently been stated by Sjollema that the harm done to certain rye crops by nitrate of soda was caused by the presence of sodium perchlorate in the material, and Erck therefore suggests the following process for its examination: 100 grammes are dissolved in 80 c.c. of water, 7 c.c. of 1·4 nitric acid added, the mixture warmed, 8 c.c. of alcohol (92° Tr.) run in, and the whole boiled for about five minutes till the reaction is complete. All the chlorine from the chlorides and chlorates will be driven off, and if the solution is made alkaline with pure sodium carbonate, evaporated to dryness and ignited, after acidifying again with nitric acid, the chlorine from any perchlorates originally present may be detected or estimated with silver in the usual manner. Should the sample contain more than 0·3 per cent. of sodium chloride, it may be necessary to employ larger quantities of acid and alcohol; but this point may be determined by testing a small portion of the liquid before the sodium carbonate is added.

Winteler objects that this process is not adapted for quantitative work, since loss of perchlorate chlorine may occur, through simple volatilization, through decomposition of the perchlorate by the chloride formed on heating (as shown by Gooch and

Kreider), and through the action of the nitric oxide evolved in the first operation. He remarks that perchlorates and chlorates are completely reduced by heating with fuming nitric acid in a sealed tube for five hours at 230°, and that in a mixture of these salts the chlorate may be decomposed by evaporation with strong HCl. Tests on potassium perchlorate, chlorate, and "pure" nitrate (contaminated with $KClO_4$) have shown the process to be perfectly reliable; and it should be equally available for treating nitrate of soda. F. H. L.

Solubility of Phosphates in Citric Acid and Ammonium Citrate. O. Foerster. (*Chem. Zeit.*, 1896, xx., 1020.)—In the following table the author has collected the results obtained on treatment with (1) ordinary Wagner solution, and (2) 1·4 per cent. free citric acid, of certain definite phosphates and also those few samples of basic slag which, out of a large number examined, have shown an appreciably different behaviour towards the two reagents. The expression "gently ignited" means that the substance was only heated sufficiently to drive off the water of hydration; and the figures given by the basic calcium phosphate explain in part the differences found by previous investigators (*cf.* ANALYST, xxi., 81 and 166). The reason of the abnormal action of slags 7 and 8 is not obvious; and Foerster is experimenting further on the subject, but it probably depends on certain double ammonium salts, formed when Wagner's liquid is employed, acting as solvents on some of the otherwise insoluble phosphates. The author remarks that he has met with several slags containing so little silica that scarcely half of the actually "available" acid was extracted by ammonium citrate.

Sample Examined.	Total Phosphoric Acid per cent.	Percentage of Total Phosphoric Acid dissolved by	
		Ammonium Citrate.	Citric Acid.

Determination of the Citrate-Soluble Phosphoric Acid in Thomas Phosphate Powder. O. Bötcher. (*Chem. Zeit.*, 1897, xxi., 168.)—The author seeks to improve upon the German official method (Wagner's) for the determination of citrate-

soluble phosphoric acid in Thomas phosphate powder. Wagner's method is open to certain objections, especially that the solutions required are different from those used for the ordinary determination of phosphoric acid in manures, which is both inconvenient and a possible source of mistakes, and that the final precipitate of magnesium ammonium phosphate is not always free from silica.

The following method was first tried: To 50 c.c. of the citrate solution of Thomas phosphate prepared according to Wagner's directions a teaspoonful of sodium nitrate was added, and the whole evaporated to dryness and ignited. The residue was moistened with hydrochloric acid and dried for two hours at 120° C. to ensure complete separation of the silica. It was then dissolved in hydrochloric acid by warming, the solution diluted with water, filtered through a small filter, the filter washed with hot water, and the phosphoric acid determined in the filtrate by the citrate method (precipitation by magnesia mixture) in the usual way. The results agreed exactly with those obtained by Wagner's method. The author did not, however, consider this method completely satisfactory, as, though simpler than Wagner's owing to the precipitation by molybdenum and the use of special solutions being avoided, it was still a somewhat intricate process.

The following method was then tried: 50 c.c. of Wagner's citrate solution of Thomas phosphate was taken, and the phosphoric acid precipitated by the citrate (magnesia) method in the usual way. The precipitate was filtered off, washed with a 5 per cent. ammonia solution, and, together with the filter, ignited while still moist, in a platinum crucible. The residue was then dissolved in warm hydrochloric acid, the solution diluted with water, filtered, the filter washed with hot water, and the phosphoric acid determined in the filtrate by the citrate method, as before. The author finds that this method yields satisfactory results. The pyrophosphate is completely reconverted into orthophosphate by the treatment with warm hydrochloric acid, and the resulting magnesium ammonium phosphate is pure and practically free from silica.

The Estimation of Potassium. A. Mercier. (*Bull. de l'Ass. belge*, 1897, x., 403-405.)—The author has proved that mercurous chloride can replace sodium formate for the reduction of potassium platinic chloride, and on this fact has based the following process: Five or ten grammes of the sample (according to its richness in potassium) are digested for an hour with 500 c.c. of cold water and filtered; 25 or 50 c.c. of the filtrate are evaporated to dryness on the water-bath after the addition of 1 c.c. of hydrochloric acid. The residue is gently ignited to expel ammonium salts, taken up in very dilute hydrochloric acid, and filtered if necessary. Ten c.c. of platinic chloride solution (10 per cent.) are then added, and the liquid evaporated on the water-bath to a syrupy consistency, cooled, and extracted with 50 c.c. of 85 per cent. alcohol + 5 c.c. of ether. The double salt is well washed on the filter with the same alcohol-ether, and then dissolved in boiling water.

The aqueous solution is brought to the boil, and mercurous chloride added little by little until it is deposited on the bottom of the beaker. In the majority of cases 2 grammes are sufficient. After five minutes' boiling the platinum is allowed to settle

to make sure that the reduction is complete, then 1 or 2 c.c. of hydrochloric acid are added and the liquid boiled again. When cold the liquid is filtered, and the platinum, which is far more dense than that obtained with sodium formate, is well washed with boiling water and ignited without previous drying in a platinum crucible. The weight of platinum obtained, multiplied by 0·4835, gives the amount of potassium in terms of K_2O. The results obtained by this method, which are tabulated at the end of the original paper, are in close agreement with those required by theory. C. A. M.

A Modification of the Schweitzer-Lungwitz Method of estimating Potassium. A. Mayer. (*Zeit. anal. Chem.*, 1897, xxxvi., 159-163.)—The method of Schweitzer and Lungwitz consists in first separating the sulphates by means of a solution of barium oxalate in hydrochloric acid, oxidizing any iron present with hydrogen peroxide, and then adding ammonia to precipitate the alkaline earths as oxalates, and iron and aluminium as hydrates. Since barium oxalate is only soluble in hydrochloric acid to the extent of 1·7 per cent. in the cold, over 800 c.c. of the solution must be used in the case of superphosphates where 15 grammes of barium oxalate are required.

In the author's modification barium chloride and oxalic acid are substituted for barium oxalate in hydrochloric acid, a course which was taken into consideration by Schweitzer and Lungwitz, and rejected by them. Twenty grammes of the substance, ash, manure, etc., are boiled for half an hour with water, the liquid cooled, made up to 500 c.c., and filtered. Fifty c.c. of the filtrate are heated, and normal barium chloride solution added from a burette, till no more precipitate is produced. An equivalent volume of normal oxalic acid solution is added, the liquid boiled for twenty minutes, and made alkaline with ammonia. After cooling, it is made up to 100 c.c., allowed to settle, and filtered. Fifty c.c. of the filtrate are evaporated in a platinum basin, the residue ignited at as low a temperature as possible to expel ammoniacal salts, dissolved in water, filtered, and the potassium precipitated by adding 10 c.c. of platinic chloride solution (containing 1 gramme of platinum in 10 c.c., and which is free from hydrochloric and nitric acids), evaporating almost to dryness. When cool, alcohol (80 per cent. by vol.) is added, and after being stirred for some time and allowed to stand, the precipitate is filtered off and dried at 120° C.

The following table shows the agreement between the results obtained by this method and those given by the ordinary method:

	Schweitzer-Lungwitz Modification. Potassium per Cent.	Ordinary Method. Potassium per Cent.
Mixture of kainite and superphosphate	7·1	7·0
Ash from iron furnace, No. 176	11·9	11·9
,, ,, ,, 187	11·1	11·1 to 11·5 (2 analysts)
,, ,, ,, 189	9·6	9·6
Potassium superphosphate ...	7·4	7·3 to 7·4 (2 analysts)

It is essential to boil the liquid for the full twenty minutes after adding the oxalic acid, or the results obtained will be too low. C. A. M.

A Rapid Method for the Determination of Silicon in Silico-Spiegel and Ferro-Silicon. C. B. Murray and G. P. Maury. (*Jour. Amer. Chem. Soc.*, 1897, xix., 138, 139.)—The authors having tried the "aqua regia" method and the fusion method of Williams (*Trans. Am. Inst. Min.*, xvii., 542) for the determination of silicon in silico-spiegel, and having found the former almost impracticable and the latter too tedious, hit upon the following method:

The sample is finely ground in a diamond mortar so as to pass through a bolting-cloth sieve. To half a gramme in a porcelain or platinum dish are added 50 c.c. of water, 10 c.c. of hydrochloric acid (specific gravity 1·20), and 12 c.c. of sulphuric acid (1 part of acid, specific gravity 1·84, to 3 parts of water), and the basin is heated until fumes of sulphuric acid are given off. When cool, about 10 c.c. of hydrochloric acid are added, heat applied, then about 75 c.c. of water added, and the liquid boiled. If there is any effervescence when the boiling ceases the liquid must be evaporated until fumes of sulphuric acid are again given off, and the residue taken up as before. The liquid is then filtered, the residue washed thoroughly with hydrochloric acid (1 : 1) and hot water, ignited in a platinum crucible and weighed. A few drops of sulphuric acid are added, and sufficient hydrofluoric acid to dissolve the silica, and the contents of the crucible are evaporated to dryness, heated to decompose the sulphates, cooled and weighed. The difference in the two weights gives the amount of silica which can be calculated to silicon.

The following are some of the results obtained by this method, which occupies about thirty minutes, compared with those yielded by the fusion method (six to eight hours):

	New Method.	Fusion Method.
1.	12·08	12·01
2.	12·37	12·25
3.	12·09	12·08
4.	13·46	13·40
5.	9·05	9·03

C. A. M.

APPARATUS.

A New Form of Specific Gravity Bottle. J. C. Boot. (*Jour. Amer. Chem. Soc.*, 1897, xix., 61, 62.)—An objection to the ordinary form of specific gravity bottle is that when the temperature of the room is much higher than the normal temperature, the liquid is continually running out of the capillary tube in the stopper during the drying and weighing. This is obviated in the bottle devised by the author, which has double walls, and in which the space between these two walls is exhausted as completely as possible.

The apparatus can be obtained from Christ. Kob and Co., Stützerbach, Germany; and from Eimer and Amend, New York. C. A. M.

THE ANALYST.

JUNE, 1897.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

The monthly meeting of the Society was held on Wednesday evening, May 5, at the Chemical Society's Rooms, Burlington House, the President (Dr. Bernard Dyer) occupying the chair.

The minutes of the previous meeting were read and confirmed.

Mr, Henry Bradford, assistant to Mr. E. G. Clayton, was nominated by the Council for election as an Associate of the Society.

The following papers were read: "The Value of the Nitrogen Factor in the Analysis of Decomposed Milks," by Alfred Smetham and J. B. Ashworth; "Notes on the Influence of Boric Acid upon the Action of Digestive Ferments," by R. A. Cripps.

ON COPPER IN PEAS.

By R. Bodmer and C. G. Moor, M.A.

(*Read at the Meeting, March* 3, 1897.)

During the last few years there have been several prosecutions for the sale of preserved peas containing copper. Three cases will be within the recollection of many of our members—the Bristol case, the Edmonton case, and the case of Grist *v.* Summers, at Southwark.

In the Bristol case the magistrates did not convict, although they expressed an opinion that the coppering of peas was objectionable.

In the Edmonton case a conviction was obtained, which was not appealed against.

In the Southwark case an appeal followed, and the matter was fought out very thoroughly. The conviction was confirmed. Shortly after this another case occurred at Southwark Police Court, which resulted in a conviction and a fine of £20 and costs.

We have thought the question of the coppering of peas sufficiently important to bring before the Society a few results of analyses of peas and other vegetables. Many of these were analyses made for private individuals, and not for the purposes of prosecution.

Methods of Analysis.—Tschirch has shown (*Das Kupfer*) that it is most important that the peas should be *completely* incinerated; this has been confirmed by Paul and Cownley and also by our own experiments. If the peas are only charred,

even nitric acid fails to extract all the copper. One hundred grammes of peas, from which the liquor contained in the tin or bottle has been poured off, are incinerated in the muffle at a moderately low temperature. The charred mass is then moistened with nitric acid and completely incinerated. The ash is taken up with nitric acid, water is added, the mixture boiled and filtered. The filtrate is evaporated to dryness, warmed with sulphuric acid till free from nitric acid, and the residue taken up with water. In this solution copper may be determined by several methods:

1. Colorimetric method with sulphuretted hydrogen.
2. ,, ,, ammonia.
3. ,, ,, ferrocyanide.
4. Gravimetric method by electrolytic precipitation.

Of the colorimetric methods, the first gives results somewhat too high. The second method gives very accurate results, if the proportion of copper is not too minute. For very small quantities of copper, the ferrocyanide method is the most accurate. On the whole, we are inclined to believe that the best results are to be obtained by electrolytic deposition of the copper on platinum.

Preserved peas are coloured with copper by heating them for a short time with a solution of copper sulphate, which is then poured off, and the peas are washed to remove all copper salt that has not actually become fixed in the pea itself.

It follows, then, that the brine in which the peas are preserved contains only traces of copper, and hence it is a point of importance to decide whether for purposes of analysis the peas should be ground up with the liquor and the mixture analysed, or whether the liquor should be first poured off and the peas analysed alone. In the analyses made by R. Bodmer the figures represent the copper in the peas alone, while those by C. G. Moor were made on a mixture of the entire contents of the tin. If the division of the sample is made by an inspector, it is easy to see that the three portions may vary very considerably in the proportion of peas and liquid they contain.

25.	Jardinières	0·52	2·09	,,

In the *Pharmaceutical Journal* of June, 1896, Messrs. Paul and Cownley published a number of figures showing the various amounts of copper found in oysters, cocoa, spirits, and preserved peas. In this paper they quote Lehmann, who "mineralizes" the sample with strong sulphuric acid, and then determines the copper colorimetrically with ammonia or ferrocyanide. They also quote the following results obtained by Vedrödi,* whose determinations were made colorimetrically with sulphuretted hydrogen, and which are given in parts per 10,000:

	Minimum.	Maximum.
Winter wheat	2·5	3·6
Summer wheat	2·5	3·0
Barley	0·1	0·9
Linseed	1·4	1·9
Peas	0·9	1·5
Mustard-seed	0·9	1·0

They conclude that according to Vedrödi some natural vegetables contain more copper than is found in vegetables to which it has been added to preserve their natural colour. Paul and Cownley proceed as follows in estimating copper in peas and other substances: The sample is carbonized in a platinum dish, and extracted with hydrochloric acid; the insoluble residue is ignited with a little nitric acid, hydrochloric acid added, and the resulting mixture is added to the original extract. The solution is then concentrated to about 30 to 40 c.c., placed in a weighed platinum dish, and the copper deposited with pure zinc. If the deposited copper is not pure copper colour, they dissolve it in a little nitric acid and estimate the copper colorimetrically. They give the following figures, which we have averaged. The figures are in parts per 10,000:

		Copper.
Oysters, average of ...	4 samples ...	2·4 nearly
Cocoa, average of ...	3 ,, ...	0·44 ,,
Spirits, average of ...	5 ,, ...	0·03 ,,
Preserved peas, average of	11 ,, ...	1·00 ,,

Of the preserved peas, their highest sample shows 1·44 and their lowest 0·54 parts of copper per 10,000.

* *Cf.* ANALYST, xxi., p. 235.

The following figures have been obtained by one of us on coffee, cocoa, flour, and barley:

	Copper.
Coffee	trace
Cocoa (entire bean) ...	0·5 grain per lb.
Flour...	trace
Barley	trace
Peas (dried)	trace

There is considerable difference of opinion as to whether the coppering of peas renders the article injurious to health. Dr. A. Tschirch has investigated this subject most thoroughly. According to him, the copper introduced in the *re-verdissage* of green peas exists chiefly as phyllocyanate, but if an excessive amount of copper is introduced, a portion is also present as albuminate or leguminate. It is immaterial in which form the copper exists, as from actual experiment on animals he has shown that the insoluble phyllocyanate is, in proportion to the amount of copper it contains, as toxic in its action as such a soluble copper salt as the double tartrate of copper and sodium. The proportion of copper required to fix the green colour of peas is very small. According to Gautier, 18 parts per million—that is, 0·126 grain per lb.—is quite sufficient for the purpose. Tschirch proposes as an extreme limit of the permissible amount of copper, one part of copper in 10,000 parts of the vegetable—that is: 0·7 of a grain per lb.—but considers that 0·35 grain per lb. is amply sufficient for the purposes of the manufacturer. It is therefore evident that the proportion of copper found in many of the samples the analyses of which we have quoted (*Das Kupfer*) is above the amount that he considers safe. As to the question whether copper is a poison, he states on page 105, as the result of experiment on animals and men and the collected cases in medico-legal practice: "We are in a position to answer this question in the affirmative, with the limitation that with men, although it seldom causes death, yet, if administered in neither too large nor too small doses, it is capable of producing more or less severe symptoms of poisoning." This is eminently a matter for the serious consideration of the proposed Committee of Reference in the new Act for regulating the Sale of Foods and Drugs.

In most European countries, with the exception of France, the addition of a copper salt to articles of food is either absolutely prohibited, or it is only permitted under certain specified limits. It is only in this country that it is necessary to argue the point as to whether the addition of a certain proportion of an injurious substance, such as sulphate of copper, does or does not render the article to which it has been added injurious to health.

Discussion.

Dr. Rideal observed that he had recently found traces of copper in a sample of sterilized milk.

Mr. Hehner thought there would be some danger in determining the copper electrolytically. Tin was always present, and this was liable to be deposited and reckoned as copper. He would not be inclined to place much faith in an electrolytic method, unless some security was afforded against the deposition of tin, and this did not seem to be an easy matter. Besides, the colorimetric process was all that could

be desired. No method could lay claim to remarkable accuracy, but the colorimetric process gave results as accurate as any other.

He could not help thinking that the quotation which the authors had taken from Tschirch's book was not sufficiently full. As a matter of fact, Tschirch had actually fed a number of his students on coppered food, and had to give them comparatively large quantities of copper to produce an appreciable effect.

It was true that in most European countries the admixture of copper with foods was prohibited by law. In Germany it was absolutely forbidden, and for some time the public analysts of that country tried to carry out the law, but soon found that it was not possible to do so, and came to the conclusion (in spite of what the law stated) that they would permit 25 milligrammes of copper per kilogramme, or about 1·7 grains per lb.

Mr. CASSAL said he would like to have the opinion of the Society on the point mentioned by the authors with regard to the treatment of samples of this nature before analysis. He had had some correspondence with Mr. Bodmer, from whom he had gained much valuable information on this subject; but he and Mr. Bodmer differed on one very important point, viz., as to whether it was necessary, under the provisions of the Sale of Food and Drugs Act, for a public analyst receiving a sample of this kind to pour off the liquor first, or to treat the sample as a whole, and analyse both liquor and peas. Mr. Bodmer thought that the proper course was to pour off the liquor and analyse the peas, on the ground that it was approximately in that condition that the peas would be eaten. Mr. Moor, on the other hand, took the view which he (Mr. Cassal) himself held, and considered it legally necessary for a public analyst to analyse the sample as submitted to him, liquor and all. He had had some legal opinions on this point, all of which agreed that a public analyst could not, in the present state of the law, do otherwise than analyse the sample as submitted to him, and that it would be sufficient to cause the failure of the case if the public analyst had to admit that prior to analysing the peas he had poured off the liquor. He (Mr. Cassal) admitted that if such a course could be considered permissible he would be very pleased, but, at the same time, he would be very sorry to advise his authorities to go into court in a case of this kind, and then have to admit that he had poured off the liquor before making the analysis, and so done a thing which it was illegal for a public analyst to do. The unfortunate result of being forced to come to this conclusion was that the figures obtained by Mr. Bodmer were rendered of but little use to other public analysts who might be engaged in cases of this kind because the standard created was one created upon Mr. Bodmer's method; and if they were told that the liquor must not be poured off, a fresh standard would be required, and the whole business would have to be refought.

Mr. BODMER said that in the Southwark case the inspector poured off the liquor in the act of dividing the sample. The inspector was asked in court if he had poured the liquor away, and answered in the affirmative, and no objection was taken by either side to this being done. In the case of the other samples, no prosecutions were intended, the analyses having been undertaken for private individuals.

Mr. CASSAL said this seemed to introduce an additional complication, and he was surprised that a legal objection on this point was not raised when the case came into

court. He understood, however, that if Mr. Bodmer were to receive a sample of preserved peas in their liquor, he would pour off the liquor as he did in the cases referred to. It seemed very necessary that some conclusion should be arrived at on this matter, and his own view was that, in the present state of the law, the only satisfactory way of stating the quantity of copper was to return the percentage of copper on the dry matter in the whole sample—peas plus liquor. It might be contended that the liquor was used in cooking, and this, indeed, was sometimes the case; and he thought it would not make a sufficiently strong case to base the analysis on the peas minus the liquor on the assumption that that was as nearly as possible the way in which they would be consumed, though no doubt this would be the most convenient way of dealing with the matter if it were legally possible to do so. He would be very glad if some conclusion could be come to on lines which would enable Mr. Bodmer's figures to be made use of.

He thoroughly agreed with Mr. Hehner in what he had said as to electrolytic methods. The method which he had himself found most satisfactory was the one followed by Mr. Bodmer, and he was bound to say that the colorimetric method with ferrocyanide was a very satisfactory way of doing the work. He was very much in favour of the ferrocyanide method of determining copper, both colorimetrically and gravimetrically.

Mr. HEHNER said that the main question turned upon what was actually sold. Was it the liquor plus the peas, or the peas alone? He had lately weighed a tin of peas marked "1 lb.," and found that the peas alone weighed 1 lb., the water being adventitious. If a butterman sold butter by the butter-fat, he could not well be proceeded against for adding water, and he (Mr. Hehner) thought that if it was the peas that were sold, and not the liquor, then it was correct to pour off the liquor and analyse the peas.

Mr. ALLEN said that in his opinion the certificate should be made applicable to the entire contents of the tin, but he would add to the results so stated the amount of copper which the peas would contain, exclusive of the water. This would afford additional information to the Bench, and show that the public analyst had taken the whole of the circumstances into consideration. He held the same opinion as Mr. Hehner with regard to the electrolytic method of determining copper. When incinerating such articles as peas for the determination of copper, it was desirable to char the substance moderately, and then add both sulphuric and nitric acid. This caused decomposition of any chlorides, and prevented possible loss of copper by volatilization. At the same time, the ash then consisted mainly of sulphates, and was far more manageable than where no sulphuric acid had been used. If the ash when obtained was moistened with a drop of sulphuric acid and nitric acid, and the product heated till fumes of sulphuric acid began to be evolved, the metals were left in such a state that on adding water any tin or lead was left entirely insoluble, while the zinc and copper dissolved.

Mr. CASSAL remarked that the fact that one grain of copper had been found in fresh peas appeared to him to be due to something abnormal. He had lately analysed several samples of French beans and peas imported into this country with a guarantee that they were not coloured with copper, without finding a trace of copper in any of

them, and it therefore seemed to him that such large quantities of copper pointed to the existence of special circumstances which were unexplained.

The PRESIDENT said that the Society was very much indebted to Mr. Bodmer and Mr. Moor for these results. It appeared to be highly desirable that more results should be collected, in order that Vedrödi's very remarkable figures might be criticised. For instance, 3½ parts in 10,000, or nearly 3 grains per lb., seemed an enormous quantity of copper to be found in wheat, though it was, of course, well known that vegetables grown in the neighbourhood of copper works, or on soils containing copper, would take up considerable quantities.

SOME ANALYSES OF WATER FROM AN OYSTER FISHERY.

By CHARLES E. CASSAL, F.I.C.

(*Read at the Meeting, February* 3, 1897.)

EARLY in 1895 I was asked to analyse certain samples of water which had been taken for the purposes of an investigation as to the alleged transmission of infectious disease by means of oysters. I was instructed to make a chemical examination of the samples as rapidly as possible, and to furnish only certain data. I therefore did not myself carry out any bacteriological tests, and these were undertaken by a distinguished bacteriologist, Dr. G. E. Cartwright Wood, whose results were subsequently published. Having regard to the erroneous views which still prevail in some quarters as to the present practical value of bacteriology in enquiries of this kind it may be useful to place the chemical facts on record, and to contrast the conclusions which could be arrived at by the aid of chemical methods on the one hand, and of bacteriological methods on the other.

We have heard a great deal about the failure of chemical analysis to afford correct and reliable information as to the pollution of water and the character of water-supplies, in certain cases; and it has become important to emphasize the facts that, at present at any rate, bacteriology, *per se*, can give us but little information of real value, and certainly cannot give us information of a decisive character.

Seven samples of water were submitted. They were taken in and about an estuary on the East Coast, where oysters are extensively cultivated, and the descriptions supplied with them were as follows:

"No. 1. P. Channel. Fattening bed for oysters. Bottom quite clean, no mud. Chance of contamination from the town of B. Example of an 'uncontaminated' oyster bed."

"No. 2. B. water. Taken opposite the town of B. A small amount of sewage runs into this water."

"No. 3. River C. a little above the estuary. Breeding ground for oysters. Nearest source of contamination is the town of W. above."

"No. 4. Taken in middle of channel opposite the town of W., and almost opposite the open end of the sewer of that town."

"No. 5. No description.

"Nos. 6 and 7 taken from oyster beds existing under the worst possible conditions."

The analytical results were as under:

	1.	2.	3.	4.	5.	6.	7.	
Date of collection	4.2.'95	4.2.'95	4.2.'95	4.2.'95	13.3.'95	13.3.'95	13.3.'95

If the results are carefully considered, with due regard to the descriptions of the places from which the samples were obtained, it is justifiable to conclude that in each case the data afford evidence of contamination; and, from a practical point of view, this is really all that is required in a case of this kind. It should be obvious that the water in which oysters or other shell-fish intended to be eaten raw are kept should be absolutely free from even the suspicion of pollution with sewage. My bacteriological colleague in the investigation has very properly pointed out that "the lesson to be learned from these and numerous similar observations is—that no molluscs should ever be permitted to be used as articles of diet which have been obtained from waters subjected to contamination, since this alone, apparently (without the presence of specific infective disease germs, such as those of typhoid fever or cholera), can give rise to most dangerous disturbances of the general health." He has further pointed out—and I am fully in agreement with him—that the only principle which can be applied in such an investigation is to judge the waters examined by the same standards as those which must be employed in judging drinking-water, so far as it is possible to do so.

The opinion given was to the effect that the results afforded evidence of contamination in each case, the data in the case of No. 4 showing pollution with matters partaking of the nature of recent sewage; and that, especially in view of the descriptions given with the samples, those numbered 2, 3, 6, and 7 yielded data indicating similar pollution to a lesser extent: while No. 1 could not be taken as affording an example of an uncontaminated water, the results in the case of this sample rather pointing to the conclusion that the oyster-bed near which it was taken was distinctly liable to "contamination from the town of B." For obvious reasons, the "oxygen absorbed" figures have not been regarded as affording evidence of much importance. They were determined and inserted in the report because they were asked for. I need not anticipate the usual, and very ancient, objections which may be raised against the drawing of the conclusions mentioned mainly from the ammonia figures; I have only to say that in this particular case these figures afford distinct and positive evidence of some contamination, which, in the circumstances named, may reasonably be regarded as due to "sewage" pollution.

I may now call attention to what could be done in the matter by the aid of bacteriology. Dr. Cartwright Wood informed me that the bacteriological examination had unfortunately afforded little or no guidance in the matter. In point of fact the

application of bacteriological methods *alone* yielded no infor
the condemnation or the passing of the samples would have bee
has stated that in judging of a water he would not trust to
alone, and that an adequate chemical analysis is necessary;
opinion, bacteriological examination frequently gives informat
great importance. A negative result from both chemical and b
tions does not, in Dr. Wood's view, in any case indicate freedo
hardly say that with these opinions I entirely concur. I do not
that I desire to condemn bacteriological processes as valueless.
contrary, that the results obtained by them, when applied
proper chemical analysis supplemented by microscopical examir
cases, be of considerable value. The application of chemical p
examination of water may be of doubtful value in certain ca
obtained, when considered alone, may mislead the investigator
over-confidence in bacteriological methods are far greater, and
ticularly threatening. I have nothing but condemnation for those who, upon
the results of inadequate analyses, habitually "pass" samples of w " perfectly
pure," "absolutely safe," and "excellent in quality." Such expressions are not
permissible under any circumstances; but what is to be said of bacteriologists who
"pass" waters upon negative bacteriological results alone?

Dr. Cartwright Wood has shown, by a series of very interesting experiments, that what may be called the "laboratory typhoid bacillus," and the "laboratory cholera bacillus" survive in sea-water, and that they can be recovered from oysters which have been purposely infected. Dr. Klein, according to a report to the Local Government Board, which forms part of the Report of the Medical Officer to the Board for 1894-95, appears to have proved the same thing. But while Dr. Cartwright Wood does not seem to attach any very great importance to the presence of the ubiquitous *Bacillus coli*, Dr. Klein attaches what I conceive to be an enormously exaggerated importance to it. The *Bacillus coli* is so universally distributed that the conclusions to be drawn from its presence are of very little value indeed; and, certainly, to draw absolute conclusions as to the existence of sewage pollution because a few of these bacilli have been found, is altogether unjustifiable, not to say absurd. No doubt the detection of a large number may afford confirmatory evidence, but that is all. The mere counting of colonies is, at the best, but a coarse and clumsy attempt to diagnose the existence of organic pollution, and by itself gives no further information than the coarsest and most clumsy of chemical processes. I contend again, as I have contended before both here and elsewhere, that no single instance can be adduced wherein the application of bacteriological methods has resulted in the detection of specific organisms, such as the typhoid bacillus or the cholera bacillus, in samples of water credited with having produced the one disease or the other. I do not mean to assert that improved bacteriological methods will not, in the future, enable bacteriologists to say with certainty that a water suspected of having produced typhoid or cholera contains, or does not contain, a germ which, when ingested by man, will, under favouring circumstances, produce either of these diseases; but I do say that up to the present time no evidence of any value has been adduced to show that this has been done. The

is essentially one which is liable to yield uncertain and mis-
l experience shows that a water yielding bacteriological results
ould justify its condemnation, will also yield results by chemical
ıpplemented by microscopic examination which would necessi-
nation. A point of considerable importance in regard to my
that, according to the report previously alluded to, Dr. Klein
ined a great number of oysters obtained from sources known to
ated with sewage, and that he found absolutely nothing of a
ept in one single case. On page 115 of the report he states that
which was described as a deep-sea oyster obtained from the
elded a pure culture of a motile cylindrical bacillus which he
ıtical with the typhoid bacillus.
he chemical results above recorded show, beyond possibility of
ers examined were contaminated, that this fact is sufficient for
ınd that bacteriological tests, carried out with the same samples,
e upon which condemnation would have been justified. The
a fact, afforded positive information; the bacteriological results did

NOTE.—Since the above paper was read, my friend, Mr. Leonard Archbutt, F.I.C., who was present at the meeting, has kindly sent me the results of two analyses of uncontaminated sea water which were made by him in 1884. Mr. Archbutt has kindly allowed me to introduce these results as an addendum to my paper. It will be seen that they fully confirm the view which I have put forward.

ANALYSES OF SEA WATER.

BY LEONARD ARCHBUTT, F.I.C.

Taken two miles off Bridlington Quay, between Bridlington and Flamborough, August 16, 1884.

	Pts. per million.
Free Ammonia	0·015
Albuminoid Ammonia	0 03

Taken off Robin Hood's Bay, near Whitby, four miles from land, August 30, 1884.

	Pts. per million.
Free Ammonia	0·005
Albuminoid Ammonia	0·03

Both samples were analysed in a fresh condition.

DISCUSSION.

Dr. STEVENSON said that on scanning the figures given it seemed to him that chemical analysis had thrown as little light upon these waters as bacteriological examination had. The estimation of sewage in sea-water was a very difficult matter, and a good deal more information was wanted in regard to it, in the direction of chemical analysis as well as of bacteriological examination.

Dr. J. A. VOELCKER said that he had been wondering when the time would come that there would be uniformity among chemists in the expression of their analytical results. It had taken him some time to calculate Mr. Cassal's figures into those that were familiar to him, and in the end he had come to much the same conclusion as Dr. Stevenson had.

There was one matter which Mr. Cassal had not mentioned, viz., the amount of nitrates in the samples. He did not know whether Mr. Cassal had the figures at hand as to the quantity of nitrates which these waters contained, but he thought they would be very material.

Mr. ALLEN desired to ask in what way Dr. Voelcker would like to see the results stated: He (Mr. Allen) thought that Mr. Cassal had hit upon a very happy way of putting the figures.

Dr. VOELCKER said that all he wished to see was uniformity of practice throughout. It seemed to him absurd to put down one factor in one notation and one in another notation; and equally absurd to adopt one system for sea-water and another for fresh water. A third system would probably be necessary in cases where sea-water and fresh water were mixed.

Dr. RIDEAL remarked that the figures of the No. 4 sample (which was evidently brackish water, containing more fresh water than any of the others) showed high saline and organic ammonia, while the oxygen absorbed was the lowest but one, and therefore the pollution, as measured by the oxygen absorbed, did not seem to throw much light on the relative value of the waters. It would have been interesting if Mr. Cassal could have given the saline and organic ammonia normally present in the sea-water of this district, free from any admixture of fresh water or possible pollution with land drainage.

With regard to the statement of results, his own practice was to give all data in parts per 100,000, which might not find acceptance in some quarters, but which, at all events, had the merit of uniformity and the approval of a British Association committee.

Mr. RICHMOND desired to ask whether, considering the large proportion of chlorides necessarily present in waters of this kind, Mr. Cassal put forward his figures given for oxygen absorbed as anything more than approximations.

The PRESIDENT said that the point referred to by Mr. Richmond was the well-known difficulty which was first pointed out before the Society by Dr. Dupré, in connection with the fact that when, as in the case of sea-water, there was a large proportion of chlorides present, chlorine was apt to be liberated by the permanganate, and this very greatly interfered with the accuracy of the results if the operation was carried out at the usual temperature of 80° F. Dr. Dupré had shown that in dealing with sea-water or brackish water it was necessary to work at a very low temperature and to use well-stoppered bottles.

In asking the meeting to thank Mr. Cassal for his paper, he would only say one word. He thought it a pity to too much disparage the help which bacteriology afforded, even if the present state of knowledge on this subject necessitated somewhat crude observations. He would certainly say for himself that waters were often submitted to him in which the chemical results were very doubtful, and in such cases the bacteriological results were of great assistance in the formation of an opinion. It was, at any rate, a known fact that in unpolluted deep well waters there was very little bacterial life, and the question of surface pollution finding its way into deep wells was one which often had to be dealt with. If only on this account, bacteriological examination must be regarded as a useful adjunct to

chemical analysis. Then, again, there was that class of waters the existence which was so prominently brought before the Society by Mr. Hehner and Dr. Dupr namely, surface wells highly contaminated in an exceedingly nitrifying soil, where there was very little free ammonia, scarcely any albuminoid ammonia, and scarcely any "oxygen absorbed." In such cases, as far as chemical results went, all there was to go upon was a proportion of chlorine which might or might not be significant (according to local circumstances), and the proportion of nitrates. In these cases the information afforded by the results of bacteriological examination was often of considerable value. Although no doubt the value of bacteriological methods was sometimes strained, it ought not to be under-estimated. He himself had subjected every water sample he had had for the past two years to a bacteriological examination, and he thought if everyone who had to analyse water would do this (without, however, in the present state of the science, attempting to look for a typhoid or following any other practically wild-goose chase of that kind), they would find the practice a very useful one.

It seemed to him a pity that there should be so many divergencies in the statement of the results of water analyses. The old fashion of stating both grains per gallon and parts per million had crept into use when Mr. Wanklyn wrote his little book on "Water Analysis." Mr. Wanklyn stated the total solids in grains per gallon, and also the chlorine, and the ammonia in parts per million, to make the figure look a little more tangible perhaps. Our Society's Water Committee had recommended, a good many years ago, a scale which was still followed, he might almost say, by every member of the Society excepting Mr. Cassal. According to that scale, every constituent was stated in grains per gallon. Dr. Frankland had introduced parts per 100,000, which was still used by some of his old pupils, but he (the speaker) thought that the majority of analysts stated their results in grains per gallon.

Mr. CASSAL said it would be seen that the sample No. 6, which was the most sea-watery of all the samples, was the cleanest with respect to organic contamination, and taking this as a sample for comparison, it was perfectly obvious that there was some organic contamination in the other samples.

With regard to Mr. Richmond's question, he did not attach great importance to the oxygen absorbed figure. He made the determinations rather as a matter of routine, and because they were asked for, and, having the results, had put them down, but it was clear that they did not afford as much information as in other cases.

The object to be kept in view in stating analytical results was to give *effective* figures—figures which were effective for the formation of an opinion. As to giving results in grains per gallon, he was sorry to find himself obliged to argue against the use of such an utterly unscientific method. "Grains" and "gallons" were barbarous measures which men of science ought to avoid the use of, whenever possible. The recommendation of the Water Committee on this point ought never to have been made. He was sorry that he could not agree with Drs. Stevenson and Voelcker, and he hoped that those gentlemen would alter their opinions on further consideration.

The statement of results was a subject that had often been discussed before the Society. He had endeavoured in the case of these samples to give as clear an idea as possible of them, and at the same time to avoid stating ineffective figures.

He did not wish the President to think that he disparaged bacteriological results. He was merely anxious to prevent misconception in regard to their value, and to prevent, if possible, reliance being placed upon them when they were put forward without any other results.

NOTES ON ALCOHOL.

By J. F. Liverseege.

(*Read at the Meeting, April 7, 1897.*)

I. Correction of Specific Gravity for Expansion.

In taking the specific gravity of more or less dilute solutions of alcohol, it is often convenient to adjust the volume of the liquid at a temperature a few degrees from 60° F., and then correct the result to 60° F. In Allen's "Commercial Organic Analysis" the following formula is given :

$$\text{Correction of specific gravity for } 1^\circ \text{ C.} = 0{\cdot}00014 + \frac{1 - \text{sp. gr.}}{150}.$$

In Hoffmann and Power's "Chemical Analysis" the correction for 1° C. is stated to be equal to 0·4 per cent. of absolute alcohol. I have calculated from these rules the correction for alcohol of several specific gravities for 1° C., and give for comparison figures taken from the table in Thorpe's "Dictionary of Applied Chemistry" (i., 45), and from that by Lyons (*Phar. Jour.* [3], xvi., 824) :

Specific gravity ...	0·85	0·88	0·92	0·95	0·98
Allen	0·00114	0·00094	0·00067	0·00047	0·00027
Hoffmann and Power	0·0010	0·0009	0·0008	0·0008	0·0005
Thorpe	0·00084	0·00083	0·00078	0·00065	0·00021
Lyons	0·00083	0·00081	0·00075	0·00061	0·00025

Owing to the differences in these results, and the amount of interpolation required in the tables of Thorpe and Lyons, an attempt was made to construct a detailed table from published work on the expansion of alcohol of various strengths. In the classical tables of Gilpin (*Trans. Royal Soc.*, 1792, 425), the weight of alcohol of various strengths contained in a 2965 grain specific gravity bottle is given for every 5° F. from 35° to 100° F. ; from the results for the temperatures from 50° to 70° F. the correction for 1° F. was obtained for forty strengths of alcohol. Another set of results was obtained from Mendeleef's specific gravity tables for 10° and 20° C., as given in Watts' "Dictionary of Chemistry." The figures of Squibb (*Phar. Jour.* [3], xv., 46, from "Ephemeris") and Tralles (Table III.) were compared with these, and also with the tables of Thorpe and Lyons before mentioned.

The result of these comparisons showed that when more than 80 per cent. of alcohol was present the corrections given by the various authorities sometimes differed by more than 0·00001 for 1° F., but that for spirits containing less alcohol than this the agreement was remarkably close. The following table is compiled from these results ; multiplication of the figures given by 1·8 will give the correction for 1° C. :

CORRECTION OF SPECIFIC GRAVITY OF ALCOHOL FOR TEMPERATURE.

Specific Gravity.	1° F. =	Specific Gravity.	1° F. =
0·794—0·864	0·00046	0·965—0·966	0·00026
0·864—0·889	45	0·966—0·967	25
0·889—0·902	44	0·967—0·968	24
0·902—0·912	43	0·968—0·969	23
0·912—0·921	42	0·969—0·970	22
0·921—0·928	41	0·970—0·971	21
0·928—0·935	40	0·971—0·973	20
0·935—0·940	39	0·973—0·974	19
0·940—0·943	38	0·974—0·975	18
0·943—0·946	37	0·975—0·976	17
0·946—0·949	36	0·976—0·977	16
0·949—0·951	35	0 977—0·978	15
0·951—0·953	34	0·978—0·980	14
0·953—0·955	33	0·980—0·981	13
0·955—0·957	32	0·981—0·983	12
0·957—0·959	31	0·983—0·985	11
0·959—0·961	30	0·985—0·987	10
0·961—0·962	29	0·987—0·990	0·00009
0·962—0·963	28	0 990—0·995	8
0·963—0·965	27	0·995—1·000	7

When the temperature is lower than 60° F. the correction given, multiplied by the difference in temperature, is to be subtracted from the specific gravity found; but when the temperature is higher, added to it.

II. Different Methods of stating Alcoholic Strengths.

The alcoholic strength of liquids is generally expressed as the percentage by weight or by volume of absolute alcohol present, or as the percentage of proof spirit by volume. Below are given formulæ for the calculation of each statement to any of the others, as well as to grammes of alcohol per 100 c.c., which is sometimes required. The formulæ are based on Squibb's absolute alcohol of specific gravity 0·7935, proof spirit containing 49·2 per cent. of this alcohol and having a specific gravity of 0·9198.

S = specific gravity at 60°/60° F.
% = grammes of absolute alcohol per 100 grammes.
v/v = c.c. absolute alcohol per 100 c.c.
w/v = grammes of absolute alcohol per 100 c.c.
P = c.c. proof spirit per 100 c.c.

(C.c. is here used to indicate the volume of 1 gramme of water at 60° F.)

$$\% = \frac{v/v \times 0{\cdot}7935}{S} = \frac{w/v}{S} = \frac{P \times 0{\cdot}4525}{S}$$

$$v/v = \% \times 1{\cdot}262\ S = 1{\cdot}262\ w/v = 0{\cdot}5703\ P$$

$$w/v = \% \times S = 0{\cdot}7935\ v/v = 0{\cdot}4525\ P$$

$$P = \% \times 2{\cdot}21\ S = 1{\cdot}753\ v/v = 2{\cdot}21\ w/v$$

Grains per fluid ounce = w/v × 4·3756, as one fluid ounce contains 437·5 grains of water at 62° F.

Statements of three important strengths of spirit are here given as calculated by these formulæ:

Absolute alcohol,	specific gravity	0·7935 = 100 % = 100 v/v	= 79·35 w/v = 175·4 P
Rectified spirit	,, ,,	0·838 = 84 % = 88·84 v/v	= 70·39 w/v = 155·6 P
Proof spirit	,, ,,	0·9198 = 49·2% = 57·03 v/v	= 45·25 w/v = 100·0 P

III. Calculation of the Results of Distillation.

If, in the distillation of an alcoholic liquid of specific gravity S L c.c. and G grammes are taken, and the distillate measures L′ c.c. and weighs G′ grammes, and has a specific gravity S′, and contains B per cent. by weight, or D per cent. by volume of absolute alcohol, or F per cent. by volume of proof spirit, as shown by an alcohol table, then the quantity of alcohol present in the liquid can be calculated by the following formulæ:

$$\% = \frac{B\,L'\,S'}{L\,S} = \frac{B\,G'}{G} = \frac{B\,G'}{L\,S}$$

$$v/v = \frac{D\,L'}{L} = \frac{D\,G'\,S}{G\,S'} = \frac{D\,G'}{L\,S'}$$

$$w/v = \frac{B\,L'\,S'}{L} = \frac{B\,G'\,S}{G} = \frac{B\,G'}{L}$$

$$P = \frac{F\,L'}{L} = \frac{F\,G'\,S}{G\,S'} = \frac{F\,G'}{L\,S'}$$

The first formula in each series is to be used when both liquid and distillate are measured, the second when they are both weighed, and the third when the liquid is measured and the distillate weighed. The above formulæ assume that the liquid and distillate are at 60° F. when measured, but for the percentage of proof spirit the correction for expansion may be made as follows, where t is the temperature in degrees Fahrenheit, and C the apparent co-efficient of expansion of the liquid, and C′ that of the distillate for 1° F. The co-efficient of expansion is equal to the correction of the specific gravity, as given in the foregoing table, divided by the specific gravity.

$$P = \frac{F\,L'[1+(60-t')C']}{L[1+(60-t)C]}.$$

If the liquid is at t° F., and is assumed to be at 60° F.

$$\text{True result} = \text{calculated} - \frac{(60-t)F\,L'\,C}{L+(60-t)C\,L'}.$$

If the distillate is at t'° F., and is assumed to be at 60° F.

$$\text{True result} = \text{calculated} + \frac{(60-t')F\,L'\,C'}{L}.$$

Applying these formulæ to cases of distillation will show that, if 50 c.c. of proof spirit are diluted and distilled to 100 c.c., an error of 1° F. in measuring the spirit will show 0·05° O.P., and that the same error in temperature in measuring the distillate will give 0·03° O.P. instead of proof strength. If 25 c.c. of whisky are diluted and distilled to 25 c.c., the result of an error of 1° F. will give 75·03 per cent. instead of 75 per cent. of proof spirit.

Corrections may also be made for errors in the calibration of the measuring vessels. If the pipette delivers L + l c.c., and is assumed to deliver L c.c. of liquid, true result = calculated $- \frac{F\,L'l}{L(L+l)}$.

If the specific gravity bottle holds L′ + l′ c.c, and is assumed to contain L′ c.c. of distillate, true result = calculated $+ \frac{F\,l'}{L'}$.

If in the measurement of proof spirit mentioned above there is an error of 0·01 c.c. in 50 c.c., the proof spirit will appear to be 0·02° O.P., or 0·01° O.P. if that error is made on the 100 c.c. of distillate. If the same error is present in the 25 c.c. specific gravity bottle, the whisky will appear to contain 75·03 per cent. of proof spirit. In most estimations errors of this magnitude are negligable. In each case it is assumed that the correct specific gravity is used for comparison with the alcohol table.

IV. Indirect Estimation of Alcohol.

Calculation of the amount of alcohol present, from the specific gravity of a liquid and from the quantity of solid matter it contains, may be used to check the results of distillation, and is particularly useful when the presence of volatile oil renders distillation unsatisfactory.

If 100 c.c. of a liquid of specific gravity S is composed of E grammes, or E′ c.c. of solid matter, and A grammes, or A′ c.c. of alcohol and water, and the specific gravity of the dilute spirit is S″, and if the ratio $\frac{S - S''}{E} = K$, where K is a constant for all usual strengths of that liquid, then $S = \frac{E + A}{E' + A'}$; and as $A' = 100 - E'$, and $A = S''(100 - E')$, and also $S - S'' = EK$, these values may be substituted, giving

$$E' = \frac{E(1 - 100K)}{S''}.$$

Tincture of iodine may be taken as an example of the application of these formulæ. I have shown ("Year-Book of Pharmacy," 1894, 477) that K = 0·008. A tincture contained 4·64 w/v of iodine and iodide of potassium, and had a specific gravity of 0·878.

The specific gravity of the contained spirit (S″) = 0·878 − 4·64 × 0·008 = 0·841.
The volume occupied by the solids (E′) = $\frac{4{\cdot}64(1 - 100 \times 0{\cdot}008)}{0{\cdot}841} = 1{\cdot}2$ c.c.

As specific gravity 0·841 = 82·9 per cent. of absolute alcohol, the tincture contained 82·9 × 0·841 × 98·8 = 68·9 w/v of absolute alcohol, while 68·6 w/v was actually present.

The volatile oil present in tincture of myrrh makes the estimation of the alcohol by distillation very unsatisfactory. I found that even after dilution and precipitation with calcium chloride and sodium phosphate, the distillate contained enough volatile oil to make the result decidedly too low. Seven samples of myrrh were made into eleven tinctures with spirit of known strength, and the solid matter and specific gravity of the finished tincture determined. From these results values of K were obtained. Nine of them varied from 0·0028 to 0·0033, one was 0·0024, and one

0·0034; as a mean result 0·003 was taken. Experiments were also made (*v. Chemist and Druggist*, xlviii., 558) which showed that the effect of the small amount of water contained in the myrrh, and of the difference of the solid matter in solution and the extract as weighed, did not seriously affect the result.

For whisky K has been found to equal 0·0055. For example, S was found to be 0·9541, and E to be 0·26 w/v. $S'' = 0{\cdot}9541 - 0{\cdot}0055 \times 0{\cdot}26 = 0{\cdot}9527$, while 0·9530 was found by distillation. This method has been found useful for checking the results of distillation; the difference between the two rarely exceeds 0·0005, and is generally less than this. As whisky rarely contains more than 0·5 per cent. of solid matter, its volume may be neglected, and the proof spirit corresponding to S″ may be taken as the alcoholic contents of the whisky.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

The Determination of Albuminoids in Milk. A. Schlossmann. (*Zeit. Physiol.*, xxii., 197; through *Zeit. ang. Chem.*, 1897, 128.)—Ten c.c. of the milk are warmed to 40° C. with 3 to 5 parts of water, and 1 c.c. of a concentrated solution of alum added. Should the flocculent precipitate not subside rapidly, an additional 0·5 c.c. of the alum solution is used, since a slight excess (up to 1 c.c.) does not affect the result. The precipitate (which in the case of cow's, goat's, pig's, and ass's milk is in medium-sized or large flakes, but in woman's milk in small flakes) is allowed to stand for some minutes, and then filtered. After having been well washed with water, the filter and its contents are extracted with ether in a Soxhlet apparatus, the nitrogen determined by Kjeldahl's method, and the amount calculated into casein.

To the clear filtrate from the casein 10 c.c. of tannin solution are added, the voluminous precipitate filtered off, washed three times with water, and the nitrogen it contains determined, and expressed as that of the soluble albuminoids (albumin and globulin).

The separation of the casein in human milk may be accelerated by the addition of a little sodium chloride during the warming, and the filtration by the addition of calcium phosphate, which mechanically prevents the fine casein flakes from passing through the filter. C. A. M.

On Mixing Dimethylamidoazobenzene with Margarine for the Purpose of affording Evidence of Identity. A. Partheil. (*Chem. Zeit.*, xxi., No. 27, 255.)—A proposal was made ten years ago by Soxhlet to make it compulsory upon margarine manufacturers to mix 1 gramme of phenolphthalein with every 100 kilos of margarine, in order to impart a "latent" colour to the product, rendering it easy of identification. There are, however, certain practical drawbacks to this plan. The phenolphthalein can easily be extracted; there is the liability to discoloration when the margarine is packed in wooden tubs which have been washed with soda; etc.

The author proposes dimethylamidoazobenzene in place of phenolphthalein. Margarine mixed with dimethylamidoazobenzene acquires a rose colour on adding a little dilute sulphuric or other inorganic acid. The proposal was brought before the chairman of the German Imperial Commission on Margarine in February, 1896, who submitted it to the Department of Public Health, with the result that the Government appeared to be favourably disposed towards the proposal.

Experiments have been made upon dogs by Professor Munk, of Berlin, who reports that long-continued dosing produced no harmful effects, and that even the administration of very large quantities produced only the same effects as corresponding doses of common salt or sugar.

Should the proposal be adopted, it will be possible for every housewife to distinguish margarine from butter, and even to detect the adulteration of butter with margarine, in very flagrant cases. H. H. B. S.

The Analyses of Butter by the Determination of the Critical Temperature. L. Crismer. (*Bull. de l'Assoc. belge des Chim.*, 1897, x., 453-481.)—In order to fix the limits of this constant, the author has made full analyses of 173 samples of butter during the course of 1896. The mean critical temperature for the twelve months was 52·5°, and the acidity of 2 c.c. of the fat was equal to 3 c.c. of $\frac{N}{20}$ alkali, making the critical temperature of the neutralized butter 55·5° with absolute alcohol. For the last six months of 1895, the corresponding figures were: Critical temperature, 52°; acidity, 2·6; critical temperature of neutralized butter, 54·6° As was pointed out in a previous communication (ANALYST, this vol., 72), the critical temperature of the neutralized butter is that of the acid butter plus the number of c.c.'s of $\frac{N}{20}$ alcoholic potash required to neutralize 2 c.c. of the butter-fat. The critical temperature was found to increase in August, it continued to rise throughout September, and reached its maximum in October.

It was shown before (ANALYST, xx., 257) that there appeared to be a certain relation between the Hehner number and critical temperature. This relation has now been confirmed, and is expressed in the following table:

		Alcohol with 9 per cent. Water.		Absolute Alcohol.	Insoluble Fatty Acids.
Critical temperature,	below ...	100°	or	54°	86—88
,, ,,	from ...	100°—108°	,,	54°—62°	88—90·5
,, ,,	,, ...	108°—118°	,,	62°—72°	90—93·3
,, ,,	,, ...	118°—124°	,,	72°—78°	93—95·5

Similarly, a ratio has been established between the Reichert-Meissl number and the critical temperature. The limits of the former for pure butter are 27-28 and 20-21, whilst the value for margarine is 3-4. The difference between the higher limit for butter and margarine = 24. With alcohol containing 9 per cent. of water, the difference between the critical temperatures of margarine and butter is 124 – 100 = 24; and with absolute alcohol, 78 – 54 = 24. Hence the sum of the Reichert-Meissl value and critical temperature of the neutralized butter gives a constant number. A long table is given, showing that with alcohol of specific gravity 0·8195 this constant is 129, and with absolute alcohol 83·5. Therefore the Reichert-Meissl value may be

obtained by deducting the critical temperature from the constant 129 or 83·5, according to the strength of alcohol employed. For example, a butter showed a critical temperature of 55° in an open tube (see ANALYST, this vol., 71) with absolute alcohol. The acidity was 2 c.c., making the critical temperature of the neutralized butter 57°. Hence the Reichert-Meissl value was 83·5° – 57 = 26·5, which result was confirmed by distillation.

With regard to the examination of butter with the refractometer, the author gives a number of results to prove that it may be misleading, and that adulterated butters may give lower figures than genuine samples. The following examples, in which the readings were taken at 40° C., are taken from his table:

	Abbe-Zeiss refracto-meter.	Insoluble Fatty Acids.	Critical Temp. + Acidity.
Butter adulterated	45·2	91·48	66·3°
,, ,, ...	45·6	91·48	67·5°
,, pure	45·8	—	57°
,, ,, ...	46	—	59·5°

The general conclusion arrived at is that, whilst this is a rapid and accurate method of arriving at the ordinary analytical data, the variation of the constant in different specimens of genuine butter is too great to allow of any certainty in the detection of small additions of margarine.

See also ANALYST, xx., 209; xxi., 241; and xxii., 21. C. A. M.

Quick Method for detecting Margarine in Cheese. R. Hefelmann. (*Zeit. für offent. Chemie*, iii., 117.)—Twenty to 50 grammes of the cheese are either grated or rubbed down with a little sand, according as it may be hard or soft, and placed in a test-tube with 20 to 25 c.c. hydrochloric acid of specific gravity 1·19. The tube is then immersed in a bath of boiling water, and heated for about half an hour, with repeated shaking. The casein dissolves to a brown or violet-red fluid, while the butter-fat separates as a clear layer, floating upon the acid solution. A drop of the fat is then removed by means of a dropping-tube, and examined by the butter refractometer of Wollny. Should the proportion of fat be too small to separate in this way, the contents of the tube may be cooled to 30° C., and 15 c.c. of petroleum ether (boiling below 70° C.) added, the whole shaken, and the petroleum ether with the fat in solution transferred to a beaker and evaporated, and the residual fat examined by the refractometer.

On continued heating, the refraction of the lower fatty acids gradually increases, until in some cases it ultimately reaches the lowest observed value for margarine. Further, in certain cases the fat of poor cheeses may show refractometer numbers up to 2·5 above the doubtful point. H. H. B. S.

Black Discoloration of a Cheese. C. Besana. (*Chem. Zeit.*, xxi., No. 28, 265.)—A sample of Parmesan cheese, covered with deep black marks resembling ink-stains, and possessing a smell like garlic, was sent to the author for investigation. A microscopical examination revealed nothing, but chemical analysis showed that the

stains were due to ferrous sulphide. The author came to the conclusion that the odour was caused by sulphur compounds, resulting from the decomposition of the protein substances, and that the iron contamination had its origin either in the water used for washing the vessels, in the vessels themselves, or in the saffron or rennet used. H. H. B. S.

The Estimation of Starch and Glycogen in Meat Preparations. A. Bujard. (*Forsch. Ber.*, 1897, iv., 47, 48.)—For the determination of glycogen, the author prefers Mayrhofer's method (*Forsch. Ber.*, 1896, 141), which he considers more simple than that of Niebel-Salkowsky (*Zeit. Fleisch und Milchhyg.*, 1891, 185). The flesh to be examined is dissolved in aqueous potash, albuminoid matters precipitated by means of hydrochloric acid and Nessler's reagent, and the glycogen, after precipitation by the addition of alcohol to the clear filtrate, is washed on a weighed filter with dilute alcohol and ether, and dried at 110° C.

The results given in I. are quite recent, whilst those in II. were obtained some time ago by the Niebel-Salkowsky method.

* In these pepper-starch could be detected microscopically, and on testing with iodine only the blue starch reaction could be obtained, whilst in all the other cases the glycogen reaction was marked.

In the author's opinion, these figures show that only in exceptional cases (where the amount is large) can the glycogen be taken as conclusive of the presence of horse-flesh, especially when the latter is mixed with other kinds of flesh. C. A. M.

Examination of Chloroform. A. Béhal and M. Francois. (*Jour. Pharm. Chim.*, 1897, v., 417-424.)—Chloroform is readily obtained pure, but rapidly alters under the influence of light and air, producing among other substances the gas carbon oxychloride. In order to prevent this decomposition, manufacturers are in the habit of adding a small amount of alcohol as a preservative. It is this alcohol, with more or less water, which constitutes the principal impurity in chloroform, and which interferes with the tests prescribed by the French Codex. The authors have found the following method of analysis satisfactory:

Detection of Water.—All the samples of chloroform examined, when submitted to a temperature of – 20° to – 40° C. by the authors, deposited crystals, which on examination proved to be ice. The simplest test is to bring some of the crystals into contact with mercuric ammonium iodide, when the latter is decomposed by the water and produces red mercuric iodide. Chloroform freed from water does not give any crystals when exposed to the low temperature, but the addition of 5 parts of 98 per cent. alcohol in 1,000 causes them to reappear.

Estimation of the Alcohol.—A modification of Nicloux's method (*Bull. de la Soc. Therap.*, iii., 860) is employed. Ten c.c. of chloroform are shaken in a separatory funnel with 4 c.c. of sulphuric acid, which combines with the alcohol. The shaking out is again repeated with 4 c.c. of sulphuric acid and then with 2 c.c. The sulphuric acid solution is mixed with 40 c.c. of water and gently distilled until the distillate amounts to 20 c.c. By this means the ethyl sulphuric acid is decomposed into sulphuric acid and alcohol.

Five c.c. of the distillate are boiled with 2 c.c. of sulphuric acid and some water, and bichromate solution (16·97 grammes per litre) is added from a burette drop by drop until a green, but not greenish-yellow, tint is reached. Each 2 c.c. of the solution corresponds to 0·01 gramme of absolute alcohol. This process is accurate if the strength of the alcoholic solution does not exceed 2 c.c. per 1,000; but if the result obtained indicates a higher amount than this, it is necessary to dilute the distillate with distilled water, and to repeat the determination.

The test experiments with pure chloroform to which a known volume of absolute alcohol had been added gave concordant and accurate results. In eight different samples of chloroform intended for anæsthetic purposes the authors found from 3 to 12·5 c.c. per litre of absolute alcohol, the mean being 6·2 c.c.

When freed from alcohol as above, the samples of chloroform answered all the requirements of the Codex. Chloroform free from alcohol ought to distil completely at 60·8° C., and the distilled chloroform should have a density of 1·500 at 15° C. In the authors' opinion, the addition of a small amount of alcohol as a preservative should be permitted. C. A. M.

Rapid Method of Analysing Guiacol and Creosotes. L. Adrian. (*Bull. de Thérap.*, January 8, 1897; through *Journ. Pharm. Chim.*, 1897, 174-176.)—This method is based on the colour reaction which nitrous acid gives with pure guiacol. From 5 to 6 grammes of the drug are shaken in a 200 c.c. flask with water (exact quantity immaterial) for two minutes, and the liquid filtered. The filtrate is diluted with water, and to 1 c.c. are added 2 drops of a solution of sodium nitrite (10 per cent.) and 1 drop of nitric acid. Pure guiacol gives an orange colour, whilst samples containing less than 50 per cent. give a quite distinct yellow colour. By preparing standard mixtures of pure guiacol and creosote, and comparing the colours given by these with that yielded by the sample, it is possible in a few minutes to judge of the approximate purity of the drug. C. A. M.

TOXICOLOGICAL ANALYSIS.

Post-Mortem Examinations for Atropine. P. Soltsien. (*Zeit. für öffent. Chemie*, iii., 115.)—Dragendorff's directions were followed in the detection of atropine in the organs and urine of a child. The importance of examining the urine in such cases is shown, and attention is directed to the extreme sensitiveness of the physiological test on the eye for identifying the extracted alkaloid. Dilatation of the pupil was obtained where the Vitali test failed to give any indication of atropine.

H. H. B. S.

ORGANIC ANALYSIS.

Determination of Glycerin in Crude Glycerin and Spent Lyes. F. Filsinger. (*Zeit. für öffent. Chemie*, iii. 97.)—While formerly the trade in glycerin was confined exclusively to the product obtained in the manufacture of stearic acid candles, etc., a large trade is now carried on in the spent lyes of soap works, from which the glycerin used in the manufacture of explosives is distilled. The determination of pure glycerin in stearin glycerin is only occasionally required, the specific gravity, boiling-point and ash, taken in conjunction with a qualitative examination, being usually sufficient. In the examination of lyes, however, this procedure does not suffice, and recourse must be had to the determination of the pure glycerin present.

The first method to come into use for technical purposes was Flemming's, which is still used by a few pharmacists. The sample is neutralized with hydrochloric acid, boiled with a slight excess of lime, filtered and concentrated to the consistence of a syrup. The glycerin is then dissolved by a mixture of absolute alcohol and ether, the solution filtered, washed with alcohol and ether, evaporated and dried at 100° C., the weighed residue, less the ash (separately determined), giving the glycerin. The weak points of the process are, first, that certain foreign organic bodies dissolve in ether-alcohol, and, secondly, that a loss is sustained in evaporation. The question, however, has been fully discussed by Hehner.

Benedict and Zsigmondy's permanganate process, founded upon the earlier

proposal of Fox and Wanklyn, is now largely used, but the process as originally devised requires modification. Instead of the calcium oxalate being converted into carbonate and then determined volumetrically, the oxalate should be dissolved in dilute sulphuric acid and titrated with permanganate. The following are working directions for determining the amount of glycerin in spent lyes by this process: 5 to 20 grammes of the sample, according to the proportion of glycerin present, are diluted, acidified with hydrochloric acid, boiled, cooled, filtered, and made up to 250 c.c. A portion corresponding to 0·2 to 0·4 gramme glycerin is transferred to a flask with about 200 c.c. water and 10 to 12 grammes potassium hydrate. Finely-powdered potassium permanganate is now added, a little at a time, until the permanent change of colour takes place. The flask is then placed on a water-bath for ten to fifteen minutes, which causes the manganese precipitate to settle out, leaving the solution red. The solution is now decolorized by the cautious addition of a solution of sodium sulphite, the solution filtered, the precipitate washed with hot water, the filtrate acidified with acetic acid and evaporated to about 100 c.c. The solution is washed into a beaker, the oxalic acid precipitated by solution of calcium acetate, the precipitate allowed to settle, filtered off, washed, dissolved in warm dilute sulphuric acid, and the oxalic acid determined by titration with potassium permanganate.

Benedikt and Cantor's acetin method, published in 1888, was used in Germany for a long time side by side with other processes, but has now been given up, owing to its unsuitability in certain cases. A method, which the author made the subject of a paper in the *Chemiker Zeitung* in 1890 (xiv., No. 102) has been used for some years by the Dynamite Company of Hamburg, and is carried out as follows: 20 grammes are dried at 100° C. for eight to ten hours, cooled and weighed. To ensure complete drying, it should again be heated for some hours and re-weighed, though, as a rule, the loss suffered the second time amounts only to a few centigrammes. The loss in weight represents the water present in the sample. For the determination of the other impurities, 5 grammes are slowly evaporated at 180° to 190° C. in a platinum basin, and the residue cooled and weighed; but in this case also it is advisable to heat a second time and re-weigh, to make sure that the weight remains constant. The water and the residue deducted from the crude glycerin gives the pure glycerin by difference. Though open to the objections to which all indirect processes are subject, the method is free from serious sources of error, and has been found in practice to give satisfactory results.

The author mentions in conclusion the proposals of Planchon, Legler, and Hehner, in which the weight of the carbonic dioxide yielded on oxidation is made to indicate the percentage of glycerin. For the successful working of all three methods, however, the glycerin must be free from foreign organic bodies, and in the case of Hehner's method the removal of chlorides is necessary. H. H. B. S.

New Method for the Determination of Glycerin. F. Bordas and S. de Rackowski. (*Ann. de Chimie Analyt.*, ii. [2], 26-28.)—This is a modification of the method for estimating glycerin proposed by Legler (ANALYST, xii., 14), and modified by Hehner (*ibid.*, xii., 44), in which the authors utilize the transition of

the tint of the solution from yellow-green to blue-green for ascertaining the end-point of the reaction. They employ a potassium dichromate solution containing 48 grammes per litre, 1 c.c. of which corresponds to 0·005 of glycerin in 5 c.c., or 1 part per 1,000. The end-point is very easily determined between the limits of 0·1 and 2 grammes of glycerin per litre, 0·1 c.c. of liquid being sufficient to effect the colour change; but outside these limits the solution requires concentration or dilution, the end-reaction being less delicate. C. S.

Estimation of Gelatin. F. Jean. *Ann. de Chimie, Analyt.*, ii. [2], 25.)—One gramme of gelatin is steeped in cold water and dissolved on the water-bath, and made up to a 100 c.c. solution; one-tenth of this is mixed with 10 c.c. of a 1 per cent. solution of pure tannin, and the whole agitated with 5 grammes of sodium chloride and 1 gramme of acid sodium carbonate, to render the gelatin tannate insoluble. After passing through a quick-running filter, the liquid is collected in a glass graduated at 45 and 60 c.c., the first-named volume being made up by washing the precipitate with a solution of sodium chloride, having a specific gravity of 1·184. A solution of iodine containing 4 grammes per litre is then added, drop by drop, until the starch test reveals the presence of free iodine, whereupon the liquid is made up to the larger volume with distilled water, and more iodine solution added until a faint blue coloration is imparted to starch. In this manner the excess of tannin is titrated, and by deduction from the original quantity gives the amount required to precipitate the gelatin. The tannin solution should always be standardized, as tannin varies in purity. C. S.

Separation of Organic Bases by Means of Potassium Bismuth Iodide. E. Jahns. (*Chem. Zeit.*, xxi., No. 27; *Repertorium*, 75.)—The author's experiments show that potassium bismuth iodide is an excellent precipitant for bases soluble in water, these can be separated almost quantitatively from extracts by its use. The reagent, which was prepared according to Kraut's directions (*Lieb. Ann. Chem.*, 1882, 210, 310), revealed the presence of choline in a number of medicinal plants, in which it had not hitherto been found; thus, choline was found in chamomile flowers, milfoil (*Achillea*), leaves of the mallow (*Malva*), anise-seed, and bark of the elder. The so-called new alkaloid "bursine," found by Bombellin (*Pharm. Zeit.*, 1888, xxxiii., 53) in *Capsella* (shepherd's purse), proved to be choline. Choline was also found in moderately large quantities in the seeds of *Lathyrus sativus* and *Lathyrus cicera*. H. H. B. S.

Determination of Iron in Blood. A. Jolles. (*Chem. Zeit.*, xxi., No. 23; *Repertorium*, p. 60.)—A weighed quantity of blood is dried in a porcelain basin and heated gently over a Bunsen burner. As soon as the mass begins to swell, the basin is cooled, and nitric acid added drop by drop. An energetic reaction sets in, and the basin must be covered to avoid loss by spurting. When the action has subsided, the basin is placed upon a triangle and heated, at first gently, but by degrees more strongly, by means of the Bunsen burner. After heating for about half

an hour over the full flame of the burner, the basin is allowed to cool, a few more drops nitric acid added, and heat again applied, gradually, as before. This operation is repeated several times, until the contents of the basin are completely incinerated. Hydrogen potassium sulphate is then added in the proportion of 1 gramme to every c.c. of blood taken, and the mixture fused. After cooling, the contents of the crucible are washed out with hot water, acidified with dilute sulphuric acid, zinc (of known iron content) added, and the iron determined by titration with $\frac{N}{50}$ or $\frac{N}{100}$ permanganate in the usual way.

The author further describes a simple method for determining iron in blood for clinical purposes. 0·05 c.c. of blood, taken from the point of the finger by suction with a capillary pipette, is placed with a little water in a crucible, evaporated to dryness and incinerated. 0·1 gramme of dry powdered hydrogen potassium sulphate is then added, and the whole fused. After cooling, the contents of the crucible are dissolved in hot water, and the iron determined colorimetrically. H. H. B. S.

INORGANIC ANALYSIS.

The Estimation of Oxygen in Air, etc. D. Albert Kreider. (*Zeit., anorg. Chem.*, xiii., 6, 418-426.)—A measured volume of air is shaken up with a strong solution of hydriodic acid, nitric oxide being present. The acid is then neutralized with potassium bicarbonate, and the liberated iodine titrated with a decinormal solution of arsenious acid. Care must be taken that all the solutions used are free from dissolved oxygen. 100 c.c. of air is a convenient quantity to work upon, and for this 15 c.c. of nitric oxide are sufficient. Experiments—seventeen in all—made by the author gave percentages of oxygen in air varying from 20·91 to 21·19. Two comparative estimations by the pyrogallol method gave 20·93 and 20·88 per cent.

The amount of oxygen dissolved in water may be determined by this method by means of the apparatus shown in the accompanying figure. The large bulb holds about 300 c.c. when filled to the mark *C*. The bulb *a* has a capacity 30 c.c. The capacity of the larger bulb must be accurately determined. The whole apparatus is completely filled with the water to be examined. Nitric oxide is then passed in by the tube *d*, the tap *b* being opened until the water sinks to the mark *C*; 2 c.c. of strong hydrochloric acid are run in through the tube *h*, the tap *d* being opened sufficiently to allow the acid to enter, and finally a solution of potassium iodide is run into the apparatus in the same way. After thoroughly shaking up the contents, the liberated iodine is titrated as described above.

The whole operation need not take more than ten minutes to carry out. The mean of twelve experiments gave 6·022 c.c. of oxygen as the amount of this gas which was dissolved in 1,000 c.cm of distilled water, at 20° C. and 760 mm. pressure.

The above method is applicable for the determination of the amount of carbonic acid dissolved in water. W. P. S.

A Modification of the Gunning Method for Nitrates. J. Fields. (*Jour. Amer. Chem. Soc.*, 1896, xviii., 1102-1104.)—The object of the modification described below is to reduce the number of reagents required, and to largely prevent the tendency to froth, which is often very troublesome in the official Gunning method.

The weighed material is gently heated with 30 c.c. of sulphuric acid containing one gramme of salicylic acid, and, while warm, six or seven grammes of potassium sulphide are added little by little, the flask being shaken after each addition. It is then placed over a low flame and the heat rapidly increased until the mixture boils. No further attention is then required, and the digestion is usually complete at the end of an hour. The potassium sulphide does double duty, it first acts as a reducing agent in place of sodium thiosulphate, and after being converted into potassium bisulphate, acts as that salt does in the original method.

The average difference between the results given by the official method and this modification when tried on sixty samples of fertilizers was 0·02 per cent., the modification giving the higher figures. C. A. M.

Determination of Oxide of Iron and Alumina in Phosphates. F. Lichtschlag. (*Chem. Zeit.*, xxi., No. 28, 264.)—Two grammes of the finely-powdered phosphate and about 8 grammes of sodium carbonate are fused together in a platinum crucible. The fused mass is dissolved in water, with the aid of 10 to 15 c.c. of dilute hydrochloric acid to remove the last portions from the crucible, and a large quantity of hydrochloric acid is then added. Altogether 100 to 125 c.c. hydrochloric acid of specific gravity 1·095 are required. The acid liquid is digested for ten minutes at 50° to 60° C., transferred to a 200 c.c. flask, neutralized with a strong solution of sodium hydrate, heated nearly to boiling, 30 c.c. of a 20 per cent. sodium hydrate solution added, and the whole digested for fifteen minutes with frequent shaking. After cooling, the flask is made up to the mark, the contents well mixed, and 50 c.c. of the filtered solution taken for the determination of the alumina.

The precipitate upon the filter is dissolved in hydrochloric acid, and the iron determined by reducing with zinc and titrating with permanganate, observing the precautions recommended by Fresenius for cases in which hydrochloric acid is present.

For the determination of the alumina, the 50 c.c. are acidified with hydrochloric acid, evaporated to dryness, taken up with a little hydrochloric acid, diluted with hot water, and filtered and washed into a beaker. The filtrate is heated to boiling, made slightly alkaline with ammonia, the precipitate allowed to settle, filtered off, and washed with hot water until the washings are free from chlorine. The filter and precipitate are then ignited and weighed. The ignited precipitate consists of $AlPO_4$. It is advisable to add a little sodium phosphate before the precipitation with ammonia. H. H. B. S.

Determination of Chromium in Ferro-Chrome and Chrome-Steel. J. Spüller and A. Brenner. (*Chem. Zeit.*, 1897, xxi., 3.)—This process has been employed in the Kladno laboratory for some years, and if the following details are attended to, it will be found very speedy as well as accurate. 0·35 gramme of the finely-powdered

sample of ferro-chrome is mixed with 2 grammes of dry powdered caustic soda in a hemispherical silver basin, and 4 grammes of sodium peroxide are sprinkled on it The vessel is heated until the mass begins to melt, the flame is then instantly removed, and the whole stirred together with a silver spatula. When the violence of the reaction has passed, the burner is again applied, 5 grammes of peroxide are added after ten minutes' fusion, and the temperature then raised till the mass becomes perfectly fluid. In half an hour 5 grammes more of peroxide are introduced, and after a further twenty minutes the oxidation will be found complete. A final addition of 5 grammes of peroxide is made to render the melt more easy of solution, and as the basin cools it is constantly stirred in order to spread the contents over its surface. The vessel is then dropped into a covered porcelain basin containing water, and in a very few minutes all the soluble matter will be extracted. After subsidence the liquid ought to be yellow; but if it be coloured green or red owing to the presence of sodium manganate or permanganate, it may be treated with more peroxide; whilst if this prove ineffectual, a few c.c.'s of a strong permanganate solution should be run in, and the whole reduced afresh. A current of carbon dioxide is then passed through the hot liquid for thirty minutes, and after cooling it is made up to 1 litre, and the chromic acid determined in 250 c.c by Schwarz's process.

In the case of chrome (or chrome-nickel) steels, 2 grammes are dissolved in 20 c.c. of strong hydrochloric acid, 10 c.c. of 1:1 sulphuric acid added, the solution evaporated, and the excess of acid removed. The residue is intimately mixed with 2 grammes of caustic soda as before, and 5 grammes of sodium peroxide sprinkled on top. The mass is heated cautiously till the sulphates are decomposed and it begins to cohere. Three more additions of 5 grammes each of peroxide are made at intervals of twenty minutes; and the melt is finally treated as above, except that it is only dissolved in 500 c.c. of water, and 250 are used for titration. When the amount of chromium is small, this is carried out by Zulkowsky's process as follows: The solution is placed in a tall beaker, 10 c.c. of 10 per cent. potassium iodide added, and pure HCl (sp. gr. 1·12) run in till the liquid is just acid. Twenty c.c. of bichromate containing 0·9833 gramme (= 0·35 gramme Cr) per litre are treated in a precisely similar manner, and after both liquids have been allowed to stand in the dark for fifteen minutes, they are titrated side by side with $\frac{N}{50}$ thiosulphate. F. H. L.

LEGAL.

IMPORTANT DECISIONS IN THE HIGH COURT OF JUSTICE.

(Reprinted from the "Times" of May 8, 1897.)

ARSENICAL SOAP.

HOUGHTON *v.* TAPLIN.

This was a case stated by the justices of Richmond upon dismissing a summons under the Sale of Food and Drugs Act, 1875.

Mr. A. Glen appeared for the appellant, and Mr. Lawless for the respondent.

An information was laid against the respondent charging him with selling to the prejudice of the appellant a drug, to wit, arsenical soap, which was not of the nature, substance, and

quality of the article demanded, contrary to Section 6 of the Sale of Food and Drugs Act. The appellant asked for arsenical soap, and he was supplied by the respondent with a tablet of Dr. Mackenzie's arsenical toilet-soap. The soap contained no arsenic. The magistrates dismissed the information, holding that though arsenical soap was a drug within the meaning of the Act, yet as the soap in question contained no arsenic it was not a drug, and no offence had been committed.

Mr. GLEN contended that the subject of the sale was a drug, though it was proved that there were no medicinal properties in the article delivered.

Mr. JUSTICE WRIGHT: Was not the article demanded a compounded drug and within the third exception in Section 6?

Mr. GLEN: It was a compounded article, but not a compounded drug.

The COURT dismissed the appeal, Mr. JUSTICE HAWKINS on the ground that the soap was not a drug, and Mr. JUSTICE WRIGHT on the ground that the soap was a compounded drug within the meaning of Sub-section 3.

FALSE WARRANTY.

DERBYSHIRE *v.* HOULISTON.

This was an appeal, by case stated, from a conviction under Section 27 of the Sale of Food and Drugs Act, 1875.

Mr. C. A. Russell, Q.C., and Mr. F. H. Mellor appeared for the appellant; and Mr. Lawson Walton, Q.C., and Mr. Reginald Brown for the respondent.

An information was laid against the appellant charging him with giving a false warranty in writing to one Martin Hopkins, in respect of certain butter sold by him and subsequently sold by Martin Hopkins to the respondent, which was not of the nature, substance, and quality demanded by the respondent, contrary to Section 27 of the Sale of Food and Drugs Act, 1875.

The respondent bought the butter in question from Martin Hopkins on September 16, 1896. It was marked "Pure butter, 10d.," but was subsequently discovered to contain 23 per cent. water. Martin Hopkins was proceeded against, but on proof that he had purchased the butter from the appellant on September 8 with a written warranty to the effect that it was "pure butter" the summons was dismissed. The appellant showed that he had purchased the butter on August 22 from Martin Malony with a written warranty that it was "guaranteed pure Irish butter." The magistrate before whom the information was heard convicted the appellant, being of opinion that it was not necessary to prove that the appellant, when he gave the warranty to Hopkins, knew that it was false, and that on the facts proved the appellant was not entitled to the protection afforded by Section 25 of the Act. It was argued on behalf of the respondent that an unlawful intention was not part of the offence.

Mr. JUSTICE HAWKINS, in allowing the appeal and remitting the case to the magistrate, said that in order to constitute the offence with which the appellant was charged it was necessary that there should be an unlawful intention. It was clear that that was the intention of the Act, because the offence was associated in the same section with three offences in which it was clear a guilty knowledge was implied. It was contended that the offence of giving a false warranty ought to be so construed as to cover the case of a person who had no knowledge that the warranty was false. It was monstrous to say that a person was liable to a fine of £20 when he believed the warranty he was giving to be true. It was true that there were cases—for instance, under the Explosives Act—where knowledge was presumed, unless the contrary were shown, but that was never done, except in cases where the Legislature had very clearly indicated that it intended to punish a man who was not morally guilty.

Mr. JUSTICE WRIGHT said that he was of the same opinion. He referred to Sherras *v.* De Rutzen, a case in which he had cited authorities in support of the proposition that a *mens rea* was essential in every offence, unless it were clearly displaced by statute. That guilty knowledge was a necessary element in the offence with which the appellant was charged was indicated by the use of the word "false," which implied a knowledge of the falsity of the warranty; it was further indicated on the principle of *noscitur a sociis* by the offence being imbedded in the same section with others, all of which implied guilty knowledge.

ERRATUM.—The second paragraph which appears on page 124 of Mr. Stoddart's paper in the previous number of THE ANALYST is misplaced. It should be read in connection with the table on page 120, to which it refers.

THE ANALYST.

JULY, 1897.

OBITUARY.

DR. C. REMIGIUS FRESENIUS.

It is with the deepest regret that we have to record the death of Dr. R. Fresenius, the Nestor of analytical chemists. Suddenly struck down by apoplexy, he peacefully passed away at midnight, June 10-11, at his home in Wiesbaden, whence for just upon half a century the results of his incessant chemical labours have flowed. Literarily and scientifically active to the very day of his death—for his work was to him ever a labour of love, and the thought of rest from work hardly had any existence with him—we have lost in Fresenius one of the few remaining eminent men who connect the present generation of chemists with the period of Liebig's greatest activity and brilliancy.

Fresenius was born at Frankfort-on-the-Maine in 1819, and was therefore in his seventy-ninth year at the time of his death. He was educated at the Gymnasium at Frankfort, and in 1836 entered as apprentice the pharmaceutical establishment of Stein, leaving there in 1840 for the University of Bonn. As a student at Bonn, he felt the necessity for a more systematic scheme of qualitative analysis than was in existence at that date, and in order to fill this deficiency he worked out such a scheme. This was published in book form in 1841 by Henry and Cohen, of Bonn, under the title, "Anleitung zur qualitativen Chemischen Analyse." It was the commencement of those books on analysis, translations of which have appeared in very numerous languages, which have made Fresenius' name a household word among chemists. In 1841 he left Bonn for Giessen, where he at once became assistant to Liebig, and there conducted the laboratory course in elementary inorganic analysis. Two years later Fresenius became "Privatdocent" at the University of Giessen, remaining there till September, 1845, when he received a call to the Chair of Chemistry, Physics, and Technology in the Agricultural Institute near Wiesbaden. The means of the Institute in question were exceedingly limited, and hardly allowed any practical chemical work to be carried on. Fresenius therefore, at the commencement of 1848, established the private laboratory with which his name is inseparably connected. Only the small number of five pupils worked with him during the first year, but their number rapidly increased, for about fifty joined him in 1855, and this necessitated the engagement of a staff of lecturers, among whom

C. Neubauer, the author of the well-known work on the analysis of urine, was the most prominent.

The teaching of Fresenius and his staff was officially recognised by the Government of the Duchy of Nassau (one of the small States absorbed by Prussia in 1866), and a financial subsidy was paid him by the State. An official agricultural and œnological laboratory was in later years combined with the establishment, which gradually became a centre of analytical research; while commercial and technological chemical investigations, touching on all branches of industry, kept a large staff of assistants employed. Though the later development of the chemical laboratories at the various German Universities largely removed the need for a tutorial establishment founded upon private enterprise, the large Institution, over all the branches of which Fresenius unceasingly watched, continued to do exceedingly good work, and to prosper scientifically and financially. When to all this is added the large amount of labour involved in the management of the journal, the *Zeitschrift für Analytische Chemie*, established by Fresenius; in the frequent issue of new editions of his works, and in the supervision of chemical manufactories, it will be seen that his was no ordinary energy. He also took an active interest in the politics of the day, and for the last few years of his life held the chairmanship of the municipality of Wiesbaden. The method of his work from morning till night, however, enabled him for just upon fifty years to fulfil his numerous self-imposed duties, and to make himself a power in chemical science—at least, in that one branch out of which, scientifically, he never stepped.

But a short time ago he expressed to the writer of this notice the hope that on the completion of the half-century of the conduct of his laboratory—which would have happened during the coming spring—he might fittingly retire.

Looking over the scientific results of his life, it can safely be asserted that no chemist of modern times since the death of Rose has left a deeper imprint upon analytical chemistry than Fresenius has. To give a list alone of the original papers written by him would cover many pages, for they range throughout the whole territory of inorganic chemistry. The most important among them are those earlier methods, such as that worked out with Will in 1843 for the valuation of the carbonates and of manganese peroxide; the use of potassium cyanide in analytical work; the differentiation of the arsenic and antimony mirrors in Marsh's process; the cyanide method of detecting arsenic in forensic cases (with Babo); his numerous contributions to the analysis of phosphates, of acetates, and of sulphates.

Much of his most careful work was done in connection with the publication of his books. He made it his duty to test almost every method of analysis which he included in his "Text-book of Quantitative Analysis"; and he conscientiously published most of the data he thus obtained. If, in this his desire to give exact information, he was often too full of detail for modern scientific taste, or if, in his anxiety to reach the highest possible accuracy, he carried decimal points somewhat farther than necessary, this does not detract from, but rather adds to, the impression which his honesty of purpose is bound to make. As in these days of specialization one chemist may find interest only in the azo-bodies, another in the derivatives of naphthalene, so Fresenius was interested only in analytical methods, and

was opposed, actively at first, passively in later years, to whatever appeared to him to stand in the way of analytical science. Thus, the doubling of many of the old equivalents, rendered necessary by the adoption of the laws of Avogadro and of Dulong and Petit, was utterly uncongenial to him, and he saw the decay, nay, the rout, of the dualistic conceptions with dismay and sorrow, and stood out, longer almost than any other writer, for the older notation.

His undying merit is, without doubt, the writing of his two works on Analytical Chemistry, in the first place, and the establishment and conduct of the *Zeitschrift für Analytische Chemie* in the second. His "Qualitative Analysis" has gone through sixteen German editions and the "Quantitative" through six. Translations exist in a multitude of languages, and every chemical laboratory in the world works according to the information contained in these volumes. In inorganic analysis they are the most trustworthy guides that were ever written.

Personally, Fresenius was of a most kindly and genial disposition; he took a loving interest in every one of his students, and inspired many of them with the enthusiasm which he so obviously felt. Not only to them will he remain in loving memory, but as long as analytical work is carried on in chemical laboratories, and as long as his methods of analysis are used in industry and in research, will the name of C. Remigius Fresenius be honoured as that of one of the worthies of chemical science.

O. H.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, June 2, in the Chemical Society's Rooms, Burlington House, the President (Dr. Bernard Dyer) occupying the chair.

The minutes of the previous meeting were read and confirmed.

The PRESIDENT announced that Dr. W. J. Russell, F.R.S., had been nominated by the Council for election as an Honorary Member of the Society. Dr. Russell, as President of the Institute of Chemistry, had worked very hard during the last three years, and had earned the thanks of the profession at large, and the Council was anxious that the Society should recognise his services by electing him an Honorary Member. (Applause.)

The following papers were read: "Note on the Presence of Heavy Metals in Cheese," by Alfred H. Allen and F. Hudson Cox; "On the Structure of the Fat Globules in Cows' Milk," by Professor V. Storch, Copenhagen (communicated by H. Faber); "On the Indirect (Tabarie's) Method for the Estimation of Alcohol," by Norman Leonard, B.Sc., and Harry M. Smith; "The Determination of Soluble Proteids by Chlorine Precipitation," by S. Rideal, D.Sc., and C. J. Stewart.

The following were taken as read: "Note on Commercial Ground Cassia," by W. F. Keating Stock; "Note on the Bacteriolysis of Gelatin," by S. Rideal, D.Sc., and Ronald Orchard.

Mr. Henry Bradford (assistant to Mr. Clayton) was elected an Associate of the Society.

Summer Meeting.

The President said that as, on account of the forthcoming Jubilee festivities, the arrangements of both town and country members during the next few weeks might be expected to be somewhat disorganized, the Council deemed it advisable that the summer meeting (which in the ordinary course would be held in July) should be postponed. It had been decided that the first meeting after the summer recess should this year be held in October instead of November, and that on either the day before or the day after that meeting there should be held what under ordinary circumstances would be the summer meeting.

NOTE ON COFFEE-PALACE COFFEE INFUSIONS.

By E. G. Clayton.

(*Read at the Meeting, March* 3, 1897.)

Eleven samples of coffee infusion supplied in coffee-palaces and similar establishments in London were lately examined by the author, with the assistance of Mr. Henry Bradford. The samples contained caffeine in proportions varying from 0·014 to 0·039 per cent., the average being 0·026. The actual figures obtained were 0·014, 0·015, 0·016, 0·017, 0·027, 0·028, 0·031, 0·033, 0·033, 0·036, and 0·039.

As a 10 per cent. infusion of coffee was found to contain nearly 0·12 per cent. of caffeine, it follows that the strength of these coffee infusions varied from about 1 to 3 parts of coffee to 100 parts of water, the average being about 2 parts per 100 of water.

Since in nearly every case the infusion was already mixed with milk and sugar, there was no method of arriving at the average probable proportion of chicory present.

ON THE VALUE OF THE NITROGEN FACTOR IN THE ANALYSIS OF DECOMPOSED MILK.

By Alfred Smetham, F.I.C., F.C.S., and J. B. Ashworth, F.C.S.

(*Read at the Meeting, May* 5, 1897.)

Having in the latter part of last year under examination a sample of milk which had undergone decomposition, it occurred to one of us that a more reliable opinion of the original composition could be obtained by estimating the nitrogen and ash, and thus calculating the original percentage of casein and albumen and ash present in the sample, than by attempting to estimate the total solids-not-fat, and calculating by any system of correction back to the fresh condition of the milk. In investigations which we had conducted upon the cheese-making industry of Cheshire on behalf of the Board of Agriculture, we had been struck by the comparatively constant contents of casein and albumen in the mixed milk of herds from various sources and at different

times; and as our experiments had further shown that the production of lactic acid commences at a very early stage of decomposition, it seemed pretty clear that any ammonia formed by fermentation of the nitrogen compounds would be fixed, and as long as the milk remained acid an estimation of nitrogen (unless free nitrogen were evolved) would yield results identical—except so far as there was loss of weight of the sample—with those obtained in the analysis of the fresh milk.

In this connection the following figures, obtained by titrating milk with KHO, using phenolphthalein as indicator, may prove interesting:

		Acidity per cent. as Lactic Acid.
Milk direct from cow		·24
,, ,, (after boiling)		·11
Mixed evening milk from vat (in evening)		·17
,, ,, ,, (next morning)		·19
(Average of 91 determinations.)		
Sept. 8. Milk, original from vat		·15
Milk kept in dairy 2 days		·70
,, ,, 3 ,, ...		·97

,, ,, 16 ,, ...		1·08
Sept. 23. Milk put up 7 p.m.		·17
Sept. 24. ,, ,, 6.30 a.m.		·18
,, ,, ,, 2.30 p.m.		·19
,, ,, ,, 11.30 p.m.		·20
Sept. 25. ,, ,, 10 a.m.		·22
Sept. 26. ,, ,, 10 a.m.		·88
Sept. 29. ,, ,, 10 a.m.		1·15

The sample of milk marked No. 8 in the tables, after being kept for thirteen weeks gave, on distillation with magnesia, ammonia = ·055 per cent., and it will be seen that up to that time the lactic acid is much in excess of the ammonia produced.

To ascertain to what extent changes in the nitrogen contents of milk took place during keeping, we started a series of experiments, the results of which we have now the honour to present to you.

The method adopted was as follows: Nine milks from various sources, of the purity of which there was no doubt, were obtained and analysed, the total solids dried to constancy at 100° C, the fat estimated by Adams' process, using Schleicher and Schüll's fat-free paper (which gave only 0·0005 gramme of residue on extraction with ether), the nitrogen estimated in duplicate by the Kjeldahl-Gunning-Arnold process, in exactly the manner described by our President (*Journal, Chemical Society*, lxvii., 811), the water of the milk being evaporated over a low flame after the addition of the sulphuric acid, the nitrogen × 6·33 stated as casein and albumin. The milk-sugar, etc., was obtained by difference.

At the same time that the quantities for the analyses were weighed out, six portions of about 10 grammes were accurately weighed in sterilized glass bottles of about 15 c.c. capacity, and these were corked, kept at the ordinary temperature of the laboratory, and the nitrogen estimated at the expiration of different periods. The following is a description of the sources of the samples of milk treated in this way:

1. Milk from a mixed herd of cows, delivered December 7, 1896.
2. Morning's milk from Cheshire Dairy Institute, December 10, 1896, being the mixed milk of 28 shorthorn and 2 Jersey cows; 20 calved March and April, 1896, and the other 10 since the middle of October. Daily rations: 4 lb. decorticated cotton-cake, 2 lb. maize meal, 2 lb. bran, and hay *ad lib.*
3. Evening's milk from above herd, December 9, sampled in morning of December 10. The cream evidently had not been thoroughly mixed with the milk.
4. Milk from 4 Dutch cows on Lord Egerton's estate, December 18, 1896; calved respectively October 30, September 31, September 28, and August 20. Food: Indian meal, linseed cake, bran, meal, hay, and mangolds.
5. Milk from 4 dairy shorthorns on Lord Egerton's estate, December 18, 1896; calved respectively August 30, August 27, June 26, and June 15. Food as No. 4.
6. Milk from 4 Jersey cows on Lord Egerton's estate, December 18, 1896; calved respectively October 24, September 15, September —, and September —. Food as No. 4.
7. Milk from 4 Kerries on Lord Egerton's estate, December 18, 1896; calved respectively August 16, June 30, February 26, and February 20. Food as No. 4.
8. Mixed morning milk from farm of Cheshire Dairy Institute, January 25, 1897. Herd and feeding same as No. 2.
9. Mixed evening milk from farm of Cheshire Dairy Institute, January 24, 1897; taken same evening. Herd and feeding same as No. 2.

The table on next page gives the original composition of the samples, the percentage composition of the solids-not-fat, the contents of nitrogen—stated as casein and albumin—and the percentage loss of weight in each sample at the time the estimation was made.

From these results it is evident that, under the conditions obtaining in these experiments, the loss of nitrogen on keeping the milk for periods up to twenty-six weeks is nil, or, at all events, does not exceed what may reasonably be deemed errors of manipulation; and it seems to us, therefore, that so long as a sample of milk has an acid reaction, an estimation of the nitrogen enables the analyst to infer with a probability amounting almost to certainty what was the original contents of casein and albumen in the sample, the only uncertainty being the loss of weight the sample has undergone on keeping.

On finding in the earlier stages of our investigation that our presumption that the nitrogen contents of a sample of milk remained constant on keeping, we obtained other samples from different sources, with a view of ascertaining to what extent the percentages of the albumen and casein varied in milk from different sources, and to what extent these enabled the analyst to infer adulteration or otherwise.

The samples examined were as follows:

10. Milk from a Liverpool dairy, stall fed, February 16, 1897. Feeding unknown.

	1. Milk from a Dairy, Rock Ferry.	2. Morning's Milk from Dairy Institute, Worleston, Cheshire, 28 Shorthorns, 2 Jerseys, Dec. 10, 1896.	3. Evening's Milk from Dairy Institute, Worleston, 28 Shorthorns, 2 Jerseys, Dec. 9, 1896.	4. Milk from 4 Dutch Cows.	5. Milk from 4 Dairy Shorthorns.	6. Milk from 4 Jerseys.	7. Milk from 4 Kerries.	8. Morning's Milk from Dairy Institute, Worleston, 28 Shorthorns, 2 Jerseys, Jan. 25, 1897.	9. Evening's Milk from Dairy Institute, Worleston, 28 Shorthorns, 2 Jerseys, Jan. 24, 1897.

11. Milk from another town dairy, February 23, 1897.
12. Milk delivered to a house at Crosby, March 9, 1897. Origin unknown.
13. Milk from a Cheshire farm near Warrington, March 10, 1897. Cows fed with clover hay, Indian corn, oats, swedes, and mangolds.
14. Mixed milk from 4 dairy shorthorns, April 1, from Lord Egerton's home farm, Tatton Park:

	Yield of Milk.		Calved.
	Morning. qts.	Evening. qts.	
"Trinket" ...	7 ...	6 ...	August 30
"Kirby Belle" ...	4½ ...	4 ...	August 27
"Cuckoo" ...	7 ...	5 ...	February 19
"Chaffinch" ...	6 ...	4½ ...	February 20

Daily rations: 2½ lb. Indian meal each a meal.
1 lb. cake each a day.
½ lb. bran each a day.
3 fodderings (with meadow hay).
2 mangolds each a day.

15. Mixed milk from 4 Dutch cows, April 1, 1897:

	Yield of Milk.		Calved.
	Morning. qts.	Evening. qts.	
"Checkmate" ...	8½ ...	7 ...	November 11
"Dutch Maid" ...	7 ...	5½ ...	November 20
"Chessboard" ...	8 ...	7 ...	December 23
"Stella" ...	6 ...	5 ...	November 1

Daily rations same as No. 14.

16. Mixed milk from 4 Kerries, April 1, 1897:

	Yield of Milk.		Calved.
	Morning. qts.	Evening. qts.	
"Kerry A" ...	5½ ...	4 ...	March 4
"Kerry K" ...	4½ ...	3 ...	February 14
"Killala" ...	5 ...	3½ ...	March 5
"Kerry No. 1" ...	3½ ...	2½ ...	January 29

Daily rations: 1¾ lb. Indian meal each a meal.
½ lb. cake each per day.
½ lb. bran each per day.
2 mangolds each per day.
3 fodderings (of meadow hay).

17. Mixed milk from 4 Jersey cows, April 1, 1897:

	Yield of Milk.		Calved.
	Morning. qts.	Evening. qts.	
"Phyllis" ...	5 ...	4 ...	October 1
"Wallflower" ...	2½ ...	2 ...	October 1
"Buttercup" ...	4½ ...	4 ...	October 24
"Tulip" ...	3½ ...	3 ...	October 1

Daily rations same as No. 14.

18. Milk taken at Stockport by inspector under Sale of Food and Drugs Act, April 13, 1897.

19. Ditto, ditto (another sample), April 13, 1897.

On analysing in the same manner as before the accompanying results were obtained:

	10. Liverpool Dairy. Town fed.	11. Liverpool Dairy. Town fed.	12. Delivered at Crosby.	13. Cheshire Farm, near Warrington.	14. From Dairy Shorthorns.	15. From 4 Dutch Cows.	16. From 4 Kerry Cows.	17. From 4 Jersey Cows.	18. From Stockport.	19. From Stockport.

*Containing nitrogen	·581	·546	·597	·576	·526	·434	·525	·639	·554	·518
Solids-not-fat	8·46	8·79	8·76	8·87	8·50	8·03	8·69	9·50	8·75	8·51
Percentage composition of solids-not-fat:										
Casein and albumin	43·50	39·36	43·15	41·15	39·18	34·12	38·32	42·52	40·11	38·54
Milk-sugar, etc.	47·40	51·87	47·95	49·60	52·23	56·91	53·51	49·69	51·09	51·24
Ash	9·10	8·77	8·90	9·25	8·59	8·97	8·17	7·79	8·80	10·22
	100·00	100·00	100·00	100·00	100·00	100·00	100·00	100·00	100·00	100·00

From the whole of the analyses it will be noticed that, with the exception of the milk from the Dutch cows, the lowest percentage (3·22) of albuminoids is in No. 9—a result slightly above that suggested by Mr. Richmond as a limit (ANALYST, xxii. 94). The average percentage of albuminoids is 3·466. If the milk from the Dutch (which gives in both cases milk of a very poor character), the Kerry, and Jersey cows, which do not as a rule form any appreciable proportion of the herds kept for the production of milk for towns' supplies, be omitted, the average percentage is 3·448.

The average percentage of milk-sugar obtained by difference is 4·45, with 4·01 as a minimum, and 4·97 per cent. as a maximum.

From the results of the analyses it will be observed that the variations in the percentages of casein and albumin are greater than those of the solids-not-fat, and consequently the nitrogen is a less satisfactory factor in determining adulteration than the sum of the total solids-not-fat. Nevertheless, as it enables the analyst to calculate with a great degree of accuracy the original contents of the casein and albumin, it offers, in conjunction with the ash, a means of control in the analysis of decomposed milks probably more accurate than any system depending upon the estimation of the total solids and a correction for decomposition, when the nature of the decomposition is unknown.

Discussion.

The President said that this contribution from Mr. Smetham and Mr. Ashworth came as a matter of considerable interest just after the suggestion lately made by Mr. Richmond, who did not know at the time that this work was in progress. One point that was brought out in these analyses was a point which Mr. Richmond had emphasized before, viz., that the most constant figure in a milk analysis was the milk-sugar. Unfortunately, however, it was the item which underwent most change on keeping. Working out the ratio of nitrogen to non-fatty solids in these analyses, he noticed that the variation was considerable, being from 1 : 14 in the case of the Kerry cows to 1 : 18 in the Dutch cows, the lowness of the non-fatty solids in the latter case probably being partly due to a deficiency of nitrogenous constituents. These Dutch cows occasionally caused trouble. He had met with cases himself in which farmers had got into trouble by relying upon Dutch cows, or by selling the milk of Dutch cows which they happened to possess, without mixing it in with the rest of the milk from a miscellaneous herd. Mr. Allen had written to him expressing regret at being unable to attend the meeting, and mentioning that he had a high opinion of the value of the nitrogen factor in the analysis of decomposed milks, and saying that in the forthcoming volume of his work on "Commercial Organic Analysis" he was suggesting a limit of 0·5 per cent. of nitrogen, which was also the figure proposed by Mr. Richmond.

Mr. Richmond said he considered the paper a very valuable one. He believed that this was the first series of systematic nitrogen determinations in milk after keeping that had yet been published, and he might say that the results agreed entirely with his own experience, although he could not claim to have made a systematic series of determinations. The most important point in the paper seemed to him to be the low proportion, both of solids-not-fat and of casein and albumin, yielded by the Dutch cows. He had had no opportunity for noticing this in his own experience, for he had not analysed any samples taken from those cows alone, which formed an infinitesimal minority among the herds from which the milk that he examined was drawn. It seemed to him, however, that the milk of Dutch cows was more or less abnormal. Similar results to those recorded by the authors had been observed in the United States at the New Jersey Experiment Station in the case of cows of a practically identical breed. The nitrogen in many cases fell distinctly below 0·5 per cent., the ash below 0·7, and the solids-not-fat frequently as low as 8 per cent. He thought that, in considering any limits that might be fixed for milk, these cows must be taken into account. It would hardly do to declare that the product of Dutch cows was not milk. The farming interest of the country would claim to be allowed to keep any particular breed of cows that they chose, and also that the normal product of these animals, whatever their breed might be, was entitled to be considered as milk. It would be for the Society of Public Analysts, or any other body that might have to fix limits for milk, to consider how far the Dutch cows would affect the figures that were chosen. In the first portion of the paper some figures were given as to the acidity of milk, estimated as lactic acid, and it was stated that milk containing 0·22 per cent. of acidity as lactic acid showed, after heating to 100° C., a

diminution of the lactic acid to 0·11 per cent. He would like to ask the authors how they accounted for this. He had himself found practically the same thing, and his own idea was that the phenomenon was to be largely accounted for by the deposition of acid calcium salts, to which a large proportion of the acidity of milk was due. He would like to know whether the authors agreed with him in this, or whether they had any other explanation to suggest. He would also like to draw attention to the fact that, in estimating the acidity of sour milk, when phenol-phthalein was used, the dissolved carbon dioxide was estimated, and the acidity, if calculated to lactic acid, would be largely in excess of the true lactic acid present. It was by no means uncommon for a milk which had been kept some time and which was distinctly sour, to show as much as 2 per cent. of lactic acid, which he believed was a quantity that was not formed by the lactic ferment; the real lactic acid would in such a case be perhaps about half this amount.

Mr. R. W. Woosnam remarked that the nitrogen determinations mentioned in the paper had all been made on samples carefully weighed out while still fresh. He did not know how the authors would deal with a sample that had been bottled up for about six weeks, the condition of which would probably be very bad indeed. He supposed they would follow the usual plan of neutralizing with caustic soda and shaking vigorously, but it would be very difficult to get a fair sample at all in such a case.

Mr. Richmond observed that an excellent method for mixing up decomposed milks was described in Dr. James Bell's work on foods. It consisted in whisking the milk with a small brush made of fine brass wire. In his own hands it had worked extremely well, determinations of fat made in sour milks agreeing very well with those made on the same milks when fresh, even when the milk was badly curdled and the cream all separated out on the top.

Mr. Cassal said he could confirm what Mr. Richmond had just said as to the possibility of mixing decomposed milks and getting fairly accurate determinations of fat in them. He thought, however, that while this could undoubtedly be done satisfactorily when the weather had not been abnormally hot, yet in very hot summers, such as had been experienced within recent years, forms of decomposition would set in which practically broke up the milk altogether, and there was no longer any possibility of getting even an accurate determination of the fat under such circumstances. He did not know whether the authors had carried out any experiments upon samples of milk which had been kept at abnormally high temperatures, but from his own experience he might mention that it was a matter well worthy of their attention. A point of interest in connection with this method, in view of the existing necessity for stating analytical details in certificates given under the Sale of Food and Drugs Act, upon samples of watered milk, was that there was nothing to prevent an analyst from forming his opinion as to the purity of a sample of milk from such a factor as the nitrogen. It was a matter of considerable interest to him to find that Mr. Richmond, Mr. Smetham, and Mr. Allen were now suggesting a limit of 0·5 per cent. of nitrogen, as he (Mr. Cassal) had had occasion to state in court that a public analyst was not bound to found his opinion upon the solids-not-fat figure, and that he might, for instance, base his opinion on the amount of nitrogen. He presumed that they would consider anything very much below 0·5 to be indicative of adultera-

tion. If satisfactory results could be obtained by using this figure, instead of making out his certificate in the form recommended by the Society of Public Analysts, a public analyst could state that the percentage of nitrogen was the basis on which he had formed his opinion. It would be interesting if the authors could give some further information with regard to the "Dutch cows" referred to in the paper. It was quite plain that a liquid drawn from a cow's udder was not necessarily milk, and he suggested that the "Dutch cow" was no better than the remarkable "single cow" whose curious products had been so often called attention to. Far more information, of a trustworthy kind, would have to be obtained before any importance could be attached to the "Dutch" and "single cow" results.

Mr. R. A. CRIPPS remarked that whenever the percentage of non-fatty solids was considered to be unduly low, it would appear desirable that the inferences drawn from this should be confirmed by a determination of the nitrogen.

Dr. RIDEAL remarked that, although the figures were conclusive as to the absence of any evolution of nitrogen under the conditions of these experiments, it was by no means certain that, under ordinary practical conditions, changes might not take place after some time, resulting in an appreciable loss of nitrogen.

The PRESIDENT said that before asking Mr. Smetham to reply he would like to mention the fact that many Dutch cows did contribute to the milk-supply of London. Dutch cows were sometimes kept by dairy farmers on account of their very copious yield of milk. They yielded poor milk, but a large quantity of it. Thanks, however, to the activity and watchfulness of companies and wholesale firms such as those for whom Mr. Richmond and Mr. Woosnam acted, a pretty sharp watch was kept upon these large milk producers, and if they kept a fair number of Dutch cows they had to keep a large number of shorthorns as well, in order to swamp the poor quality of the Dutch milk. During the two previous years of drought a good many samples of milk had been sent to him by indignant vendors, who had received unpleasant letters from the wholesale dealers whom they supplied, on account of their milk coming dangerously near to or just passing the limits prescribed by the Society of Public Analysts. But in years of drought there was no doubt a tendency for all milk to be rather poor, and then the poverty of the Dutch cows very often made its effect felt, despite the mixture of the milk with that of shorthorns. He did not think many people would keep Dutch cows only, or that, if a man kept only a few cows, he would choose Dutch ones, as it would be too risky. What the Society of Public Analysts was hoping for was to obtain a legal definition of milk, or, rather, to get powers given to that Reference Committee which it was hoped would be legally constituted, to declare from time to time a definition of milk which would have the force of law. Then, no doubt, if it were decided that when a purchaser asked for "milk" he was entitled to get something containing 8·5 per cent. of non-fatty solids and so much fat, the vendor would use Dutch cows at his own risk and peril. A magistrate would probably take a lenient view in such a case if the man could prove the genuineness of his milk; but what they hoped was that they would get, through legal machinery, some such definition as would at any rate leave the *onus probandi* on the vendor in the case of anything falling below the limit fixed. Phenolphthalein always seemed to him to be a misleading indicator to use for determining acidity in a fluid

like milk, determining, as it did, the carbonic acid, which did not represent acidity in the sense of the term as used in reference to milk.

Mr. SMETHAM said that, although Dutch cows appeared to be used to some extent in the South, they had not, except in a few instances, penetrated to any large extent into the North. Lord Egerton, however, had on his estate a considerable herd, and it was from this herd that he (Mr. Smetham) had obtained all the samples of milk from Dutch cows which they had examined. It was, perhaps, unfortunate, but he figured out from the cost of feeding, the production of milk, etc., in the case of the last four Dutch cows, as compared with shorthorns and Jerseys fed at the same time, that the Dutch cows were the most profitable. The quantity of butter yielded per day by the shorthorns was 4·05 lb.; the Dutch cows gave 4·33 lb., the Kerrys 3·96 lb., and the Jerseys 4·50 lb. Of casein and albumin together the shorthorns gave 3·66 lb. per day, the Dutch 3·80 lb., the Kerrys 2·63 lb., and the Jerseys 2·87 lb. The Jerseys were, therefore, the most profitable from a butter-making point of view, but for cheese-making the Dutch were undoubtedly the most valuable, giving much more casein than any of the others. From the point of view of the farmer, whatever they might be from the consumer's point of view, the Dutch were undoubtedly the most economical cows to keep. With regard to the variations that had been alluded to, it had been pointed out in the paper that any calculations based upon the nitrogen factor were not as accurate throughout the whole of these tests as those based on the total solids-not-fat. Of course, the percentage of solids-not-fat recorded in the case of the Dutch cows would in itself represent about 7 per cent. of adulteration; if the percentage of solids-not-fat had been normal, no doubt the nitrogen would have been higher. He might mention that on several previous occasions he had examined milk from Dutch cows, and had always found it exceedingly poor, generally containing less than 8·5 per cent. of non-fatty solids. His experience, however, had been limited entirely to Lord Egerton's estate, and possibly there might be something in the climate or soil of that part of the country which gave rise to these abnormal results. So far as feeding was concerned, these cows were treated in exactly the same way as the Jerseys, which gave 9½ per cent. of solids-not-fat. They had used phenolphthalein as an indicator because of its very easy working and the very accurate results that it gave, but the figures for acidity stated in the paper represented the total acidity, from whatever source, and he did not for a moment wish to assume that it was all due to lactic acid. It was very possible, though he was not prepared to say that it was so, that the explanation suggested by Mr. Richmond for the loss of acidity in the milk after boiling was the correct one. He himself, however, rather preferred to look upon it as due to the presence of carbonic acid; but he had made no experiments to prove this, and only knew that they obtained in the milk as it came from the cow a result higher than that given by the same milk after it had been carried from the cow and mixed in a vat. The next day they took some milk direct from the cow and boiled it, and found that there was the dimunition in acidity which they had referred to, and which he attributed, rightly or wrongly, to loss of carbonic acid. With regard to Mr. Woosnam's remarks, he desired to point out that, although these samples were carefully weighed out while the milk was fresh, any difficulties

caused by bad condition of samples would have to be dealt with, whatever might be the mode of analysis. Difficulties from this cause were inherent to the analysis of a decomposed milk, but he thought the nitrogen determination would probably be affected in a less degree than any other. It would scarcely be possible to take 20 grammes for the determination of the total solids or the ash, but this quantity could be taken for the nitrogen determination, and was, in fact, about the best quantity to work on. This was a great advantage in favour of the Kjeldahl process. With regard to the temperature at which the experimental samples had been kept, there had been no attempt made to regulate it. The samples were in small bottles closed by corks, the bottles having been first sterilized. They were kept for a period extending from December, 1896, until the end of April, 1897, when some of these determinations were made, and although there had been no hot weather, some of them had occasionally been subjected to a rather high temperature, for at times the laboratory temperature rose as high as 70° F. So far as the experiments had gone, there was no appreciable loss of nitrogen, but they had been careful not to say that there could not be loss of nitrogen under conditions other than those under which the experiments were carried out. The Worleston milk was from an experimental farm belonging to the Cheshire County Council, and the feeding of the cows was as stated in the paper. He had for two years carried on experiments on this farm, and there was no doubt that very often, from one cause or another, the total solids of this milk fell to 8·5 and even lower. No doubt, as Mr. Bevan had said, the ash was a very constant constituent of milk, and a very good indication of its purity or otherwise, but it needed to be determined with considerable care. It was not an uncommon thing for inexperienced operators to get results that were too low, owing to volatilization of alkaline salts resulting from the use of too intense a flame. There was also the objection that if boric acid or a borate were present, the calculation was upset. He had made some experiments with regard to the percentage of phosphates in the ash of milk, and had found that phosphates formed a very constant constituent. The advantage, however, which the nitrogen had over the ash was that, except in the shape of ammonia salts, there was no very easy way in which a milkman could add any nitrogenous compound to the milk, and few would be likely to know how to add ammonia salts, or where to buy them.

NOTES ON THE INFLUENCE OF BORIC ACID UPON THE ACTION OF THE DIGESTIVE FERMENTS.

By R. A. Cripps, F.I.C.

(Read at the Meeting, May 5, 1897.)

The widespread employment of boric acid as a preservative of milk, fish, and other articles of food renders the subject of this short paper of the greatest importance.

It seems probable that the few simple experiments herein recorded have been long ago carried out on behalf of those whose commercial interests are largely influenced by the use of preservatives for food, but the fact that the results of any

such experiments have not, so far as I am aware, been hitherto recorded, must serve as my excuse for bringing so simple a matter before you this evening.

For the purposes of experiment the following were employed:

1. *Amylolytic ferment*—(*a*) as infusion of malt, (*b*) as saliva.
2. *Proteolytic ferment*—(*a*) as pepsin, (*b*) as zymin.
3. *Milk-curdling ferment* as chymosin.

I. Amylolytic Ferment.

(*a*) *Infusion of Malt.*—This was applied by a modification of the method of determining the diastatic power of extract of malt, described by me in the *Pharm. Journal*, 3rd Series, xx., p. 481. For this process three solutions are required: (1) Perfectly smooth potato-starch mucilage 1 per cent. (2) Malt liquor, prepared by digesting 1 part of good ground malt with 10 parts of distilled water at a temperature of 50° to 55° C. for an hour, and filtering. (3) One per cent. solution of iodine in KI.

Solutions 1 and 2 being raised to 38° C., 50 c.c. of 1 was introduced into each of a series of bottles, together with 50 c.c. of distilled water, containing the following quantities of boric acid: None, 0·01, 0·02, 0·05, 0·1, 0·2, 0·5, and 1·0 gramme. When the temperature was properly adjusted 5 c.c. of the malt solution was added to each, the bottles replaced in the bath, and small portions of each tested with iodine solution after five, seven, ten, and twelve minutes. In every instance digestion was complete at the end of twelve minutes, although not quite completed in ten minutes.

(*b*) *Saliva.*—One part by volume of fresh saliva was mixed with 9 parts of distilled water and strained. Into each of a series of bottles was introduced 10 c.c. of starch solution, with 12 c.c. distilled water containing boric acid in proportion to yield 1·0, 0·5, 0·2, 0·1, 0·05, 0·02, 0·01, and 0·0 per cent. of the final volume, raised to 38° C., and 2 c.c. of saliva solution added.

These were digested on the water-bath at a temperature of 38° C., the liquors being tested with iodine in the ordinary way. After four minutes all showed the red dextrin reaction, and all starch was *completely* converted in the following times:

0·2 per cent. boric acid after eight and a half minutes.
0·5 per cent. and 1·0 per cent. boric acid after nine minutes.
0·01 per cent. and ·05 per cent. boric acid after ten minutes.
0·02 per cent. boric acid after ten and a half minutes.
None and 0·10 per cent. boric acid after eleven and a half minutes.

II. Proteolytic Ferment.

(*a*) *Pepsin.*—For each experiment 5 grammes of white of egg in a fine state of division were mixed with 100 c.c. of water acidulated with 1 per cent. (vol.) of hydrochloric acid of officinal strength, the whole raised to 38° C., and the following proportions of boric acid added together with 5 c.c. of a 2 per cent. solution of pepsin—boric acid: (1) none, (1*a*) none, (2) 1 per cent., (3) 0·5 per cent., (4) 0·2 per cent., (5 and 5*a*) 0·1 per cent., (6 and 6*a*) 0·05 per cent., (7 and 7*a*) 0·02 per cent., (and 8 8*a*) 0·01 per cent. Digestion of Nos. 2, 3, and 7 was complete in forty-five minutes; Nos. 1, 4, 5, 5*a*, 6, and 8*a* in fifty minutes; and of Nos. 1*a*, 6*a*, 7*a*, and 8 in one hour. As is usual in such experiments, those in which digestion was most retarded showed

practically complete digestion by the time the first was completed. The tests, however, indicate that even 1 per cent. of boric acid does not retard peptic digestion.

(*b*) *Zymin.*—The proteolytic action of this ferment was determined by a modification of the U.S.P. process for pancreatine as follows:

(1) A solution was prepared containing 0·25 per cent. zymine and 0·75 per cent. sodium bicarbonate.

(2) A 1 per cent. solution of boric acid in fresh milk.

Solution No. 2 was mixed with such proportions of fresh milk as to produce 1·0, 0·5, 0·2, 0·1, 0·05, 0·02, and 0·01 per cent. boric solution.

These, and also a blank containing milk alone, were raised to 42° C., 25 c.c. of the zymine solution added and maintained at 35° to 38° C.

To test for completion of peptonization, to 1 c.c. of nitric acid of 2 per cent. by vol. were added 5 c.c. of the mixture. After thirty minutes, digestion in none of the liquids was completed, 20 c.c. more zymine solution was added, and the tests continued at intervals of about ten to fifteen minutes. After two hours twenty minutes all except that containing 1 per cent. boric acid no longer curdled when tested, and after two and a half hours even this was also digested.

III. Milk-curdling Ferment.

For this test 100 c.c. of fresh milk at 38° C. were rapidly mixed with 1 c.c. of a 2 per cent. solution of Blumenthal's chymosin and set aside. Similar experiments were made with milk containing from 0·01 to 1·0 per cent. of boric acid as before. In every instance a fine curd was produced in from six to seven minutes, that containing 1 per cent. of boric acid being certainly the firmest.

The practical result of these tests is that in so far as the processes of digestion in a living frame are represented by such experiments in glass vessels, such processes are not influenced by the employment of boric acid in quantity considerably in excess of that necessary for preservation of food; the question of its employment for such purposes would seem rather to turn upon the results of an inquiry into the physiological action of the acid when absorbed into the blood.

Pending such an investigation, it appears to me that the use of boric acid in reasonable proportion can scarcely with justice be made the ground of prosecution under the Food and Drugs Act.

Discussion.

The President said it was interesting to note that these results agreed closely, at any rate in the matter of peptic digestion, with the results of some similar experiments carried out by Mr. Hehner six or seven years previously. Mr. Hehner had taken white of egg, and pepsin, and dilute hydrochloric acid made up to represent gastric juice, and added varying quantities of boric acid up to about 1 per cent. of the whole solution. The conclusion Mr. Hehner came to was that peptic digestion was not in any way retarded by the boric acid. He pointed out, however, as Mr. Cripps had done, that this did not necessarily carry with it the inference that boric acid was harmless, for it was not known what it might or might not do when absorbed into the system. Some work had been done, he believed, in

America, previously to Mr. Hehner's experiments, with regard to the possible interference of boric acid with diastatic fermentation, and it was also then found not to have any retarding effect.

Mr. RICHMOND said that the experiments referred to by the President as having been made in America were probably those of Messrs. Leffmann and Beam, the results of which were published in the ANALYST nearly ten years ago. He would like to ask Mr. Cripps if the zymine which he used was that which was known as Fairchild's preparation. He (Mr. Richmond) was under the impression that Fairchild's preparation was supplied, mixed with the requisite quantity of alkali, and if Mr. Cripps had added alkali to this the solution would probably be too alkaline. He did not know whether, if this were the case, it would have any appreciable effect on the action of the boric acid.

Dr. RIDEAL said he thought he was correct in saying that, in addition to Messrs. Leffmann and Beam's experiments, some investigations had been made by H. A. Weber (*Journ. Amer. Chem. Soc.*, 1892, p. 4) as to the influence of boric acid on peptic digestion; and he had himself published in the *Pharmaceutical Journal* ("Year-book of Pharmacy," 1894, p. 443), the results of some experiments on papain digestion, in the presence of different acids, and found that boric acid made the least variation in the amount of digestion. He thought that, although boric acid might have no retarding influence upon normal digestion, its physiological action, as Mr. Cripps had mentioned, might be more marked. What public analysts, however, were concerned with was whether or not it was a "foreign" substance, and not whether it did or did not retard digestion. He considered that one very important point in connection with all artificial digestive experiments was that it was not correct to regard the disappearance of the substance experimented upon as the measure of the digestive action. That the starch or albumin dissolved by no means proved true digestion to have taken place. The starch might be converted into soluble starch, or the albumin into albumose, neither of which reactions constituted true digestion. The measure of the digestion of albumin was its conversion into peptone, and the measure of the digestion of starch was its conversion into dextrin, or, possibly, sugar.

Mr. S. F. BURFORD said that in some towns it was the practice for milkmen to take out milk and leave it in small shops during the whole day, collecting what remained unsold in the evening. He had met with more than one sample of milk that had been exposed in this way, and although the milk was chemically unobjectionable, its odour and taste were very bad indeed. It was scarcely necessary to remark that it would not be possible to leave milk exposed in this manner without any change being apparent, unless boric acid or some other preservative had been added to it; and he thought that this alone was a sufficient argument against the use of such substances.

Mr. CASSAL said that boric acid and borax were foreign substances, and therefore adulterants. They ought not to be present in articles of food unless their presence was acknowledged. If they were present, the purchaser had a right to be made acquainted with the fact. The mere fact that a preservative like boric acid was present in the food in sufficient quantity to produce its specific effect in retard-

ing or preventing the decomposition of that food was enough to show that its presence must affect the process of digestion. If such experiments as those described could be taken to represent what went on in the animal body, the conclusions drawn from them by the author might be justifiable; but such experiments could not be taken as representing the actual processes going on in the body in any way, and he presumed that Mr. Cripps would not seriously contend that they could. There was distinct evidence, on the other hand, that when boric acid was introduced into the animal body it produced injurious effects. A case had recently occurred in the neighbourhood of Dover, in which it was shown apparently beyond all doubt that fowls had been injuriously affected, and that some children had also been injured, by the ingestion of food containing boric acid. The food was a pudding made with milk containing rather a larger quantity of boric acid than was generally present, owing to the addition of the preservative by both the wholesale and retail vendors. Evidence had also been adduced which showed that boric acid and borax injuriously affected the kidneys; it had been recently used in the treatment of certain nervous diseases. The late Sir Andrew Clark, Sir Henry Thompson, and other well-known medical authorities had expressed themselves strongly on the subject. From the point of view of the public analyst, the presence of a foreign substance in a food constituted adulteration, and when the physiological effects produced by the ingestion of that foreign substance were even only doubtful, an offence of a serious character was constituted in the absence of any acknowledgment of the admixture. He regarded the addition of boric acid preservatives to milk, at any rate, as a grave offence indeed when the fact of the admixture was not disclosed, and nothing that the author had said could excuse or palliate that offence. The unacknowledged addition of so-called "preservatives," "sweeteners," and "antiseptics" to articles of food was largely on the increase, and it was a serious public evil.

The PRESIDENT observed that it was desirable to know whether the actual production of pepsin might not be retarded, even in the absence of any interference with its action in the stomach.

Mr. CRIPPS said that he had not been aware of the papers by Messrs. Leffmann and Beam and by Mr. Hehner, but was pleased to know that his own results were in accord with theirs. In reply to Mr. Richmond's question, he might say that he had used Fairchild's preparation of zymine as it was sold to him (containing one part of zymine to three parts of sodium bicarbonate), without any further addition of alkali. His own opinion was that the disappearance of the starch or albumin gave a very good indication of digestive power. He had, in fact, in the case of the experiments with starch, tested up to the point of complete digestion, namely, until iodine gave no more colour. There were certainly difficulties in the case of albumin, but he thought decidedly that the time taken to produce a given result was a very fair indication indeed of digestive power. A great many experiments in connection with the subject of peptic digestion had been published which confirmed this view. He could not agree with the opinion held by some that because boric acid was a substance foreign to milk, its use should be entirely prohibited. It was exceedingly difficult to keep milk, and he ventured to think that there existed practically a necessity for some preservative, provided that the use of such preservative could be shown to be harm-

less. Boric acid was in use to an enormous extent, and in this way had stood the test of experience for several years; if it was used in reasonable quantity he did not think any case could be brought forward proving it to be harmful. Its possible effect upon the production of pepsin, to which the President had alluded, was a question entirely for the physiologists, and one which he (Mr. Cripps) was quite unable to deal with.

The PRESIDENT said that, having regard to the present state of the physiological problem, he did not think it could be said that the addition of boric acid was an adulteration unless it was undeclared; but if its presence were undeclared, since boric acid was undoubtedly a foreign substance, the case was different, for anything sold as milk which contained an added foreign substance ceased to be milk, even irrespectively of the possibly injurious nature of the article added. Whether it should be considered illegitimate to sell milk containing boric acid, even with a declaration, on the ground that it contained a substance injurious to health, was a problem that undoubtedly was not yet solved, although the fact that, in small quantities, boric acid could not be very injurious to ordinary adult members of the population might almost be said to have been proved statistically, since we nowadays consumed so much of it in bacon, sausages, herrings, butter, and other substances besides milk. In the case of milk, however, the question might assume a very serious aspect, because infants were fed on milk, and it was possible that boric acid might have some injurious effect upon infants. Until this part of the question was satisfactorily settled by physiologists, he did not think that the unrestricted use of boric acid ought to be sanctioned. If it were made absolutely necessary to declare its presence, the public could then use their own discretion as to whether or not they would buy milk containing it, and they would have the option of getting milk free from preservatives for use in feeding infants. Whatever individual opinions were held in connection with this subject, he was sure it would be agreed that thanks were due to Mr. Cripps for his paper. Although some of the work might not be new, it was none the less interesting on that account, for confirmatory work by independent observers was always valuable.

NOTE ON THE PRESENCE OF HEAVY METALS IN CHEESE.

BY ALFRED H. ALLEN AND F. HUDSON COX.

(Read at the Meeting, June 2, 1897.)

IT will be within the recollection of those present that a paper was recently read before the Society by Mr. F. W. Stoddart, describing a sample of Canadian cheese in which he found metallic lead. In the discussion of that paper one of us made the statement that it was within his knowledge that sulphate of zinc was sometimes added to cheese. As this fact appeared to be outside the experience of most of the members of the Society, we have been at some trouble to ascertain how far the practice is still extant.

With this object we wrote to druggists in business in various parts of Wiltshire, asking to be supplied with samples of "Cheese Spice," that being the name by which

the preparation is locally known. In due course we received two samples of so-called "Cheese Spice," but other druggists to whom we applied stated that they did not sell it. Examination of these two samples showed one to be crystallized sulphate of zinc, while the other consisted of a solution of sulphate of zinc of such a strength as would correspond to 38 per cent. of the crystallized salt.

It appears that the "Cheese Spice" is used to prevent the heaving and cracking of cheese.

The question next suggested itself whether the zinc used remained in the curd or passed away in solution in the whey, and to settle this point we prepared a small quantity of cheese by means of rennet, adding sulphate of zinc in the proportion of 1 gramme to the gallon of milk, which is about that in which it is directed to be used. As a consequence we find that 99·28 per cent. of the total zinc employed passed into the curd, the remaining 0·72 per cent. remaining in solution.

Mr. R. Bodmer informs us that he quite recently found zinc in two specimens of cheese sold in Southwark, which were submitted to him under the Sale of Food and Drugs Act. One of these was a pale-coloured cheese, similar in appearance to Cheddar, and contained 0·84 grain per lb. of zinc, corresponding to 3·7 grains per lb. of the crystallized sulphate. The other sample was a reddish cheese, more like Gloucester, and contained 0·56 grain per lb. of zinc, corresponding to 2·5 grains of the crystallized sulphate.

From these facts there is no doubt that the practice of adding sulphate of zinc to cheese is not obsolete, although it is apparently dying. There can be little doubt that the zinc in the samples analysed by Mr. Bodmer owed its origin to the practice we have described, and we would suggest that the metallic lead found by Mr. Stoddart had its origin in the addition of some preparation of lead, probably the acetate, to the cheese.

It is within our knowledge that sulphate of copper was formerly added to cheese, and it is well-known that the green mould in certain kinds of cheese has been imitated by the insertion of copper or brass skewers.

Instances are on record of chromate of lead having been found on the outside of cheese, its presence being attributed to the cheese having been wrapped in a yellow cloth.

Mr. A. Wynter Blyth, in his work on "Foods," states that in past times instances have occurred in which preparations of arsenic have been added to cheese as a preservative, and that in 1841 several persons were poisoned by these means. A similar case occurred in 1854, when a Parisian family suffered, but not fatally.

Discussion.

The President said it seemed very curious that a substance of this kind should be used at all. There was not the slightest necessity for the use of any kind of antiseptic in cheese-making except salt. At the best it could only be required as a corrective for very slovenly dairy work. It was unfortunate that Dr. Stevenson was not present, for he had at one time paid a good deal of attention to the toxic action of small quantities of zinc.

Mr. BEVAN remarked that the bottle containing the solution bore no "poison" label.

Mr. ALLEN said that zinc was not in the poison schedule, hence such a label was not legally required.

Mr. HARVEY thought that zinc would act as an emetic rather than as a poison.

Mr. BODMER said that this was on a line with the question of copper in peas. Continued small doses would probably have a much more serious effect than a single large dose.

Mr. HARVEY remarked that copper was a cumulative poison, whereas zinc was not.

Mr. BODMER said that in the matter of toxic action zinc was by some authorities ranked higher than copper, while by others it was regarded as lower than copper.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Critical Examination of the Iodine Number of Lard. W. Meyer. (*Zeit. für öffent. Chemie*, iii., 134.)—Samples of lard examined during the past two years gave 65·0 and 54·9 as the highest and lowest iodine numbers, whilst the average of thirty-four samples was 59·4. The samples giving iodine numbers above 60 came through Hamburg houses, and were probably of American origin, whilst those with the lower iodine numbers were from small home slaughterers. In none of the samples could admixture of foreign fat be detected.

A recently-examined sample gave the low iodine number 49·7, and although, according to Späth and Neufeld, so low a number is possible, the sample was further tested for cocoa-nut-oil and beef-fat—the only adulterants ever used—but no evidence of either could be obtained.

Two other samples from reliable sources gave 50·8 and 52·1.

In three cases, in which the lard was prepared in the laboratory from different descriptions of pig-fat, the iodine numbers were 47·5, 49·8, and 58·4.

The author agrees with Mansfeld in fixing the upper limit at 65·5, and with Neufeld in placing the lower at 46·0. H. H. B. S.

Determination of Caffeine in Coffee. A. Forster and R. Riechelmann. (*Zeit. für öffent. Chemie*, iii., 129.)—Twenty grammes of ground roasted coffee are boiled four times with 200 c.c. of water, the extract made up to a litre, filtered, and 600 c.c. of the filtrate placed in an extraction apparatus with some chloroform. Solution of sodium hydrate is then added to alkaline reaction, and the whole digested with chloroform for ten hours. The chloroform extract is now transferred to a flask, the chloroform distilled off, and the nitrogen determined in the residue by Kjeldahl's

method, the caffeine being calculated from the nitrogen found. A sketch is given in the original paper of the apparatus which the authors used for the extraction.

In the course of their experiments, the authors found in aqueous coffee extract a body which they believe to be identical with the new alkaloid which has been named "coffearine" by Paladino. The new alkaloid is precipitated by picric acid, is insoluble in chloroform, and fails to give the murexide reaction, by which characteristics it is distinguished from caffeine.

In order to ascertain the relative proportions of the two alkaloids in coffee, the authors determined the total alkaloid nitrogen and the caffeine nitrogen, assuming the difference between the two to represent the nitrogen existing as coffearine. In this way they obtained the following results with three different sorts of coffee:

Nitrogen as Coffearine.	Nitrogen as Caffeine.
0·154	0·344
0·203	0·320
0·043	0·370

H. H. B. S.

On the Determination of Caffeine in Coffee and Tea. A. Hilger and A. Juckenack. (*Forsch. Ber.*, 1897, iv., 49, 50.)—Twenty grammes of the finely-powdered tea or coffee (previously dried in the water-oven in the case of unroasted coffee) are extracted with 900 c.c. of water for several hours at the ordinary temperature, and then completely exhausted by boiling with water. The extract is cooled to about 60 to 80°, 75 c.c. of a solution of basic aluminium acetate (liquor aluminii acetici of the German Pharmacopœia) added, and then by degrees with continual stirring 1·9 grammes of sodium bicarbonate. After being boiled for five minutes, the liquid is cooled, brought to a total weight of 1,020 grammes, and filtered. Seven hundred and fifty grammes of the clear filtrate (corresponding to 15 grammes of the original substance) are mixed with 10 grammes of precipitated aluminium hydrate and some paper pulp and evaporated to dryness. The residue is well dried in the water-oven and extracted for eight hours with carbon tetrachloride in a Soxhlet apparatus. The solvent is evaporated and the residue of caffeine, which is quite colorless, is dried and weighed.

Where absolute accuracy is required, the nitrogen in the crude caffeine is determined by Kjeldahl's method, and the result calculated to water-free caffeine, 1 c.c. of $\frac{N}{10}$ sulphuric acid corresponding to 0·00485 gramme of caffeine. The results obtained in this way are 2 to 4 milligrammes less than those yielded directly. The carbon tetrachloride requires to be purified by shaking with 5 per cent. soda solution, washing with water and drying with calcium chloride before it can be used for the extraction. C. A. M.

On the Relation between the Amount of Caffeine and Quality of Chinese Tea. L. Graf. (*Forsch. Ber.*, 1897, iv., 88, 89.)—Kellner has shown that in the living tea-plant the amount of caffeine in the leaves decreases with the growth.

Since the finer sorts of tea consist of young leaves, it occurred to the author that the percentage of caffeine might serve as an indication of the quality. Two varieties of tea were examined, and the caffeine was estimated by making an aqueous extract, precipitating the tannin with basic lead acetate, filtering, removing the lead, concentrating the filtrate after the addition of sodium acetate, again filtering and extracting the caffeine with chloroform.

The results calculated on the air-dried tea were :

	No.	Caffeine, per cent.	Price, Marks.
Souchong	206	2·96	1·30
,, ...	273	3·10	1·80
,, ...	266	3·53	3·15
Congou	270	2·82	1·80
,, ...	269	3·70	2·40
,, ...	268	4·09	3·10

Thus in both kinds of tea the amount of caffeine increases with the quality and commercial value. C. A. M.

Estimation of Theobromine in Cocoa and Chocolate. L. Maupy. (*Journ. Pharm. Chim.*, 1897, v., 329-332.)—Five grammes of cocoa, from which the fat has been extracted with petroleum spirit, are triturated with 2 c.c. of water and then boiled under a reflux condenser for an hour with a mixture of 15 grammes of phenol and 85 grammes of chloroform. When cool the phenol-chloroform extract is filtered, and the residue twice decocted for thirty minutes with 15 grammes of chloroform, the decoctions being added to the filtered solution. The chloroform is evaporated, and 40 grammes of ether are added to the residue and left for six hours. The theobromine is precipitated, while the caffeine, colouring matter and last traces of fat remain in solution. The precipitate is collected on a weighed filter, washed with several c.c. of ether to remove phenol, dried, and weighed.

In the case of chocolate, 10 grammes are finely powdered, and the fat extracted with petroleum spirit. The residue is mixed with 4 grammes of 70 per cent. alcohol, and the estimation continued as if one were working on the 5 grammes of cocoa. When the proportion of sugar in the chocolate is more than 50 per cent. the quantity of phenol in the solvent is decreased, so that about 0·6 gramme of phenol are used for each 1 gramme of cocoa.

The following results were obtained in this way with samples of roasted cocoa :

	Theobromine, per cent.
Cocoa Trinidad	1·44
,, Caracas	1·38
,, Para	1·28
,, Grenada	1·60
,, Martinique	1·52

A chocolate containing 60 per cent. of sugar yielded 0·54 per cent. of theobromine.

It is stated that the alkaloid is white or only slightly colored, even in the case of roasted cocoa and chocolate.

C. A. M.

Analysis and Composition of Liquorice Extract. G. Py. (*Journ. Pharm. Chim.*, 1897, 280-284.)—*Moisture.*—Ten grammes of the liquorice extract are dried for seven hours at 100°.

Ash.—The residue from the above is used for the estimation of the soluble and insoluble ash.

Alcoholic Extract.—This is found by dissolving 2 grammes of the extract in about 30 c.c. of water, cooling, and adding alcohol so as to make the mixture contain 75 per cent. After being stirred, the precipitate is allowed to settle for twelve hours, then collected on a filter and washed with 75 per cent. alcohol. The filtrate is evaporated, and the residue dried at 100° C. and weighed.

Ammonium Glycyrrhizate.—The alcoholic extract from the previous determination is dissolved in hot water and precipitated with sulphuric acid (1 : 10). The precipitate, after having been washed with water acidulated with sulphuric acid and then with distilled water, is dissolved off the filter by concentrated ammonia. The ammoniacal solution is evaporated, and the residue dried at 100° and weighed.

Organic Substances Precipitated by Alcohol are estimated by deducting from 100 the percentage of total ash, moisture, and alcoholic extract.

As a rule, these five determinations enable one to judge of the commercial value of a liquorice extract; but further information may be obtained by determining the nitrogen by Kjeldahl's method. The nitrogen belonging to the glycyrrhizin can be found by multiplying the amount of the latter by 0·0593.

Reducing Sugars are determined in the filtrate from the glycyrrhizin precipitate.

Detection of Gelatin.—Gelatin ought always to be looked for, since it is of frequent occurrence in liquorice extract, either fraudulently or to give suppleness to liquorice-sticks, and to prevent their sticking to the paper. It is tested for in the portion insoluble in 75 per cent. alcohol, which is dissolved in hot water and then cooled.

C. A. M.

ORGANIC ANALYSIS.

Some Colour Reactions of Tartaric, Citric, and Malic Acids. E. Pinerua. (*Ann. de Chimie Analyt.*, ii. [4], 66.)—The reagent employed is a freshly-prepared solution of 0·02 gramme of β-naphthol in 1 c.c. of sulphuric acid (specific gravity 1·83), from 10 to 15 drops being added to about 0·05 gramme of the acid under examination, the mixture being carefully and slowly warmed in a porcelain capsule.

Tartaric Acid.—Blue coloration, changing under the influence of heat to a decided green. When cooled and diluted with 15 to 20 volumes of water, the liquid becomes a persistent yellow-red.

Citric Acid.—Intense blue colour unchanged by a continuance of heat, but disappearing (or turning pale yellow) on dilution. The admixture of a small quantity of tartaric acid suffices to develop the characteristic green; a dull blue-green indicates 10 to 12 per mil. of this acid.

Malic Acid.—Greenish-yellow on progressive heating, turning to bright yellow, and becoming bright orange on dilution.

The reactions of the other organic acids are much less distinct than the above. In case of mixtures the acids should be separated before the test is applied. When the coloration begins to appear, the capsule should be withdrawn from the flame and only heated again in order to verify the change. C. S.

Research on Geranium-Oil. E. Charabot. (*Bull. Soc. Chim.*, 1897, xvii., 489-492.)—It has been shown that geranium-oil contains a mixture of two isomeric alcohols, geraniol and citronellol, which rotate the beam of polarized light in opposite directions. The author's experiments were made with the object of determining whether optically active esters were also present. For this purpose the samples were saponified, and the product distilled in a current of steam. In all cases there was a sensible diminution of the rotatory power. It was observed that the less volatile portion of the saponified essence had the disagreeable odour of the part passing over between 200° and 210°, when geranium-oil is fractionally distilled.

The results obtained with oils of known purity were as follow :

Origin.	Per Cent. Ester as Tiglate of Geranyl.	Free Alcohol as $C_{10}H_{18}O$.	Total Alcohol.	Specific Gravity at 15° C.	Rotatory Power l=100 m.	Rotatory Power after Saponification.	Lowering of Rotatory Power.

INORGANIC ANALYSIS.

Analysis of Aluminium and its Alloys. F. Jean. (*Ann. de Chimie Analyt.*, ii. [4], 61-65.)—It is important to determine the proportions of metals and metalloids in aluminium, on account of their influence on the physical and mechanical properties of the metal; and the methods proposed by Moissan and Gouthière (ANALYST, vol. xxi., pp. 83 and 270), though complete, do not exhaust the subject.

The author acts cautiously on 10 grammes of metal with 10 per cent. hydrochloric acid, absorbing the evolved gases in a Will and Warrentrapp bulb-tube containing bromine; the solution thus obtained is afterwards heated to drive off the bromine, the *sulphur* thrown down as barium sulphate, and the *arsenic* precipitated by hydrogen sulphide. This latter precipitate is heated with fuming nitric acid, and so converted into arsenic acid, in which form it is weighed, any *antimony* present remaining undissolved as oxide, when the precipitate is again taken up with water. *Phosphoric acid* is determined from the filtrate by boiling, treating with 5 c.c. of nitric acid and 10 c.c. of concentrated ammonium nitrate, and precipitating with ammonium molybdate, the Pemberton method of titration being adopted.

The solution of the metal is diluted and filtered, *carbon* being determined from the loss on ignition of the residue dried at 100° C. The remainder of the residue is fused with potassium nitrate and alkali carbonates and taken up with boiling water, *silica* being rendered insoluble by evaporation to dryness with a little hydrochloric acid, whilst the other constituents are re-dissolved in nitro-hydrochloric acid and united to the main solution. From this solution *lead* is thrown down (in the absence of tin and antimony) by hydrogen sulphide, the precipitate being ignited, dissolved in nitric acid (with a few drops of sulphuric acid), and estimated as sulphate. *Copper* is precipitated from the filtrate by boiling with sodium hydroxide. Should *tin* or *antimony* be present, the sulphide precipitate is treated with yellow ammonium sulphide, and these metals estimated in the usual way.

A colorless filtrate from the hydrogen sulphide treatment indicates the absence of *chromium* and *nickel*, and in that event it is concentrated to 100 c.c., one half of which (= 5 grammes of metal) is treated with potassium chlorate, and evaporated to dryness to remove *silica*, which is fused with alkali carbonate and again separated to ensure absence of alumina. The filtrate is then treated with 25 to 30 c.c. of hydrochloric acid and titrated for iron with stannous chloride. *Manganese* and *zinc* are determined in the second 50 c.c. of solution. This is rendered alkaline by sodium hydroxide, boiled to dissolve the alumina, and treated with bromine to precipitate *manganese*, *zinc* being titrated with sodium sulphide.

When *chromium* is present, a separate portion of substance is taken for the estimation of this element and iron, 1 gramme being carefully attacked by sodium hydroxide, and afterwards fused with potassium nitrate and sodium bicarbonate, taken up again with water and filtered. The insoluble oxides are dissolved in dilute sulphuric acid, and the solution, after being reduced by zinc, is filtered off and titrated with permanganate for *iron*. *Chromium* is estimated in the solution colorimetrically, 50 c.c. being compared with an equal volume of standard solutions of neutral potassium chromate.

Nitrogen may be determined by passing through 10 c.c. of decinormal acid the gas resulting from the action of a solution of sodium hydroxide (S. G. 1·32) on 5 or 10 grammes of metal, distilling when the reaction is terminated, and titrating the ammonia by decinormal alkali.

The Moissan method of *sodium* determination may be advantageously modified by converting the nitrate into sulphate and then into carbonate (by calcination with ammonium carbonate), removing the sulphuric acid by baryta-water, and titrating this sodium salt (instead of the chloride) by decinormal acid. C. S.

The Separation of Iron from Aluminium. **F. A. Gooch and F. S. Havens.** (*Zeit. anorg. Chem.*, xiii., 6, 435-440.)—The method is based upon the solubility of ferric chloride in a mixture of equal parts of concentrated hydrochloric acid and anhydrous ether, aluminium chloride being practically insoluble in this medium. A number of results given show that the method is accurate, when carried out in the following way: The mixed chlorides are dissolved in a very small quantity of water; about 15 c.c. of a mixture of concentrated hydrochloric acid and ether are added,

and the whole cooled to 15° C. Hydrochloric acid gas is now passed in until the solution is quite saturated. Five c.c. more ether are added, and hydrochloric acid gas again passed in. The aluminium chloride is filtered off through an asbestos filter, washed with the above acid and ether mixture, which must be saturated with hydrochloric acid gas, and dried for half an hour at 150° C. The precipitate is then heated for some time with one gramme of mercuric oxide, and finally ignited over the blow-pipe. By this treatment the chloride is converted into oxide. An alternative method is to dissolve the precipitated aluminium chloride in dilute acid, and to precipitate with ammonia in the usual way. If much iron is present a green oily layer separates out on the addition of the acid and ether solution, consisting of an ethereal solution of ferric chloride. An excess of ether prevents the formation of this layer. W. P. S.

Determination of Nickel in Nickel-steel. J. Spüller. (*Chem. Zeit.*, xxi., 26, 243.)—A number of standard samples of nickel-steel filings are provided, in which the percentage of nickel is accurately known. For testing steels containing from 1 to 7 per cent. of nickel, it is sufficient to have three such standard samples with 1, 3, and 5 per cent. of nickel respectively. Two grammes of the sample to be tested, and 2 grammes of one or more of the standard samples, are each boiled with about 60 c.c. of nitric acid of 1·2 specific gravity in ¼-litre flasks until completely dissolved and fumes cease to be given off. After cooling, the iron is precipitated with zinc oxide, the flasks are made up to the mark, shaken, the precipitates allowed to settle, and the liquids filtered off, the green-colored filtrate from the sample under examination being compared with the corresponding filtrate from the standard samples.

H. H. B. S.

The Estimation of Vanadium by means of Organic Acids. Philip E. Browning and Richard J. Goodman. (*Zeit. anorg. Chem.*, xiii., 6, 427-434.)—On boiling a solution of ammonium vanadate with an excess of tartaric acid, the vanadic acid is reduced to the tetroxide, which may be titrated with a standard solution of iodine, after neutralization with sodium bicarbonate.

Tungstic acid is not reduced by tartaric acid, and its presence has no influence on the estimation of vanadic acid, whilst molybdic acid is readily reduced.

Experiments on the action of tartaric acid on vanadic acid in the cold proved that the reduction to the tetroxide was complete, provided that the solution was concentrated, and the time of action extended to one day, whilst under similar circumstances tungstic and molybdic acids showed no signs of reduction. Vanadic acid may therefore be estimated in the presence of both of these acids.

Oxalic or citric acid may be used in the place of tartaric acid. An excess of oxalic or tartaric acid has no influence on the estimation, but too large an amount of citric acid must not be used, as it tends to give somewhat high results.

The amount of organic acid used should be, approximately, ten times the amount of the vanadic acid to be estimated. It will be found better, in titrating the

tetroxide, to add a slight excess of the standard solution of iodine, and then to titrate this back with a standard solution of arsenious acid, using starch as an indicator. W. P. S.

The Reaction of Filter-paper. L. Magnier de la Source. (*Ann. de Chimie Analyt.*, ii. [5], 82-84.)—Having, contrary to the experience of R. Gans, found that on boiling tartar along with the filter-paper a slight error in excess always results, the author studied the reaction of several kinds of filter-paper, and found:

1. Ordinary filter-paper boiled in water colored rose by 1 drop of alcoholic phenolphthalein solution and 2 drops of lime-water, left the colour unaffected, but when decolorized by 1 c.c. of decinormal sulphuric acid, 0·0015 gramme of the latter was absorbed; this does not, however, prove combination of the acid with the cellulose of the paper, but may be merely due to the presence of earthy carbonates.

2. French "Berzelius" paper behaved in a perfectly neutral manner under the same treatment.

3. Schleicher and Schüll's "Berzelius" paper, washed with hydrochloric acid and hydrofluoric acid, immediately decolorized the indicator, and the restoration of the colour required an amount of lime-water equal to 0·0014 gramme of sulphuric acid.

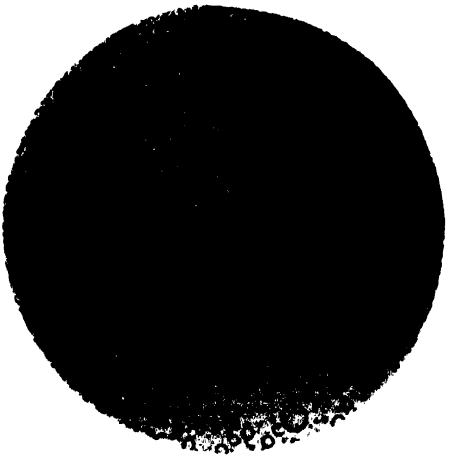
4. Swedish "Berzelius" paper, over fifty years old, showed, before washing, a degree of acidity equivalent to 0·0003 gramme.

5. The same paper, washed with very dilute hydrochloric acid followed by distilled water till the washings were neutral, and dried in presence of potassium hydroxide, gave an acid reaction to the extent of 0·0008 gramme of sulphuric acid.

6. After the same paper had been subjected to prolonged washing with boiling water, its acidity declined to 0·0002 gramme, *i.e.*, about its initial degree.

The necessity for washing the filter with boiling water to remove the final traces of acidity, which would falsify the titration of alkali tartrate, is thus apparent, especially since even 0·0005 gramme of acidity will cause an error in excess of 0·2 gramme of tartrate in 10 c.c. C. S.

APPARATUS.



The Serrin Balance for Quick Weighings. A. Démichel. (*Rev. de Chim. Analyt.*, v. [2], 25-27.)—The distinguishing feature of this balance is that weights and riders of less than 1 decigramme are dispensed with, their place being taken by a chain, one end of which is suspended from one arm of the beam, and the other supported by a lever mounted in the case and capable of elevation or depression at will, whereby the effective weight of chain on the balance is adjusted. This weight is recorded by a graduated scale attached to the lever and sliding behind a vernier in one of the uprights of the case.

In weighing, the ordinary weights are employed to approximately balance the substance, the final adjustment being made by lowering the chain, and as this can be done without interruption or opening the case, the operation can be performed more rapidly than usual. The chain appliance can be fixed to any balance with a beam long enough to allow the chain to hang freely between the column and the pan.

THE ANALYST.

AUGUST, 1897.

OBITUARY.

Mr. F. M. RIMMINGTON.

We regret to announce the death, on June 17, of one of the oldest members of our Society, and one of the oldest Public Analysts in England, viz., Mr. F. M. Rimmington, Public Analyst for the boroughs of Bradford and Dewsbury. Mr. Rimmington was a pharmacist in Bradford for fifty years. He had always taken an active interest in the detection of adulteration of food and, perhaps more especially, of drugs; and on the passing of the Sale of Food and Drugs Act, he was appointed Public Analyst for the boroughs already mentioned, and retained those appointments until the time of his death, which occurred at the ripe old age of seventy-eight. He was the author of a number of papers, most of which have been published in the Journal of the Pharmaceutical Society, but some of which, on analytical subjects, have appeared from time to time in our own pages. Notwithstanding his advanced age, he still took an active interest in both analytical and general scientific work, and especially in microscopy. He was a man of striking personality, and will be missed, not only in his own town, but by a large number of friends and correspondents all over the country. Mr. F. W. Richardson, who was for many years Mr. Rimmington's assistant, has been appointed to succeed him as Public Analyst for Bradford.

B. D.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

ON THE STRUCTURE OF THE "FAT GLOBULES" IN COW'S MILK.

By Professor V. Storch, Copenhagen.

Translated and Communicated by Harald Faber.

(*Read at the Meeting, June* 2, 1897.)

From the analyses of the butter and butter-milk derived from the same churning the composition of the serum of the butter and the serum of the butter-milk can be calculated. By "serum" is understood the aqueous portion, *i.e.*, everything in the butter except fat and salt, and in the butter-milk everything except the fat. It will be found that the butter-serum always contains much more albuminoids and much

less milk-sugar than the serum of butter-milk. This will be seen from the following table, which shows the average composition of the butter and butter-milk from ten different churnings, the cream being churned both fresh and after ripening:

COMPOSITION OF BUTTER AND BUTTER-MILK.

	From *fresh* cream.		From *ripened* cream.	
	Butter.	Butter-milk.	Butter.	Butter-milk.
Albuminoids	0·64	3·28	0·84	3·37
Milk-sugar	0·35	4·98	0·39	4·58
Ash	0·14	0·79	0·16	0·81
Water	13·03	89·74	13·78	90·93
Fat	83·75	1·21	82·97	0·31
Salt	2·09	—	1·86	—
	100·00	100·00	100·00	100·00

From these figures the composition of the butter-serum and the butter-milk-serum can be calculated, as is shown in the following table:

COMPOSITION OF SERUM OF BUTTER AND BUTTER-MILK.

	From *fresh* cream.		From *ripened* cream.	
	Butter.	Butter-milk.	Butter.	Butter-milk.
Albuminoids	4·52	3·32	5·54	3·38
Milk-sugar	2·47	5·04	2·57	4·60
Ash	0·99	0·80	1·05	0·81
Water	92·02	90·84	90·84	91·21
	100·00	100·00	100·00	100·00

It will be seen that the serum of butter made from fresh cream contained 1·20 per cent. more albuminoids and 2·57 per cent. less milk-sugar than the serum of the butter-milk, and somewhat similar figures were found for the products derived from ripened cream. It is evident that the serum of butter cannot contain more of the serum derived from butter-milk than would correspond to its content of milk-sugar. In the serum of butter from fresh cream there can only be $\frac{2{\cdot}47}{5{\cdot}04} \times 100 = 49{\cdot}01$ per cent. of serum of butter-milk; and similarly that of butter from ripened cream can only contain 55·87 per cent. of the serum of butter-milk. If from the serum of butter this calculated amount of the serum of butter-milk is deducted, there will remain a *residue* consisting of albuminoids, ash, and water, which will have the following composition:

COMPOSITION OF THE RESIDUE FOUND BY CALCULATION TO BE PRESENT IN

	Butter from *fresh* cream.	Butter from *ripened* cream.
Albuminoids	5·67	8·27
Ash	1·18	1·36
Water	93·15	90·37
	100·00	100·00

This residue was found to be of very similar composition in all the ten churnings

where the cream had been churned fresh; and in all the ten churnings with ripened cream it also had almost the same composition as the average given above, but, as will be seen, there was a difference in the composition of this residue according as to whether it was derived from fresh or from ripened cream. The proportion between fat and residue in the butter was found to be almost the same in both series of churnings, inasmuch as 100 parts of fat corresponded to 8·62 and 8·07 parts of residue from fresh and ripened cream respectively. This discovery, made several years ago, led me to conclude that a certain relation could be found between the fat and this residue, and that perhaps this aqueous albuminoid forming the residue was connected in some way with the fat globules in the milk.

I therefore made a careful investigation of the albuminoids in butter by the following method: From 1 to 2 lb. of butter were melted at a low temperature until the butter-fat had clarified. The total content of serum and salt separated out as a white viscous mass. The butter-fat was carefully decanted off, the serum rinsed twice with benzene, afterwards diluted with distilled water, and carefully mixed with one and a half times its volume of strong alcohol. A white flocculent precipitate formed, which contained nearly all of the albuminoids from the butter, together with some salt. This was separated by filtration, washed with 60 per cent. alcohol, and extracted with ether until all fat was removed. On drying in the air at the ordinary temperature, this precipitate was converted into a very fine white powder. After drying, it was extracted with distilled water and washed until the washings were free from salt, and then treated with a 0·2 per cent. solution of sodium hydrate. Under this treatment it swelled very much, and formed a stiff gelatinous mass which could take up a considerable amount of water without losing its gelatinous consistency. Stirred up in a large quantity of water, the voluminous gelatinous precipitate slowly settled; it could only be separated from the liquid by filtration with extreme difficulty. After being washed by decantation, brought on to a filter, and treated with strong alcohol, it did not lose its gelatinous consistency. By subsequent washing with ether and drying in the air it formed a fine, loose, hygroscopic powder of grayish-white colour having the following properties. It was insoluble in water, alcohol, and ether, almost insoluble in acetic acid and dilute mineral acids at the ordinary temperature. In very weak solutions of sodium hydrate or ammonia it swelled considerably without dissolving. It dissolved slowly and incompletely in a dilute solution of sodium hydrate, and was precipitated therefrom by an acid. Even in concentrated solutions of sodium or potassium hydrate it dissolved very slowly and incompletely at the ordinary temperature, somewhat more quickly on heating; it then formed a light, yellowish-brown spongy mass. When swollen in water it gave the reactions characteristic of albuminoids—Millon's reaction, that with iodine, and the biuret reaction. It contained a considerable quantity of sulphur, of which only a small quantity was removed by boiling with alkalies. Treated with warm dilute hydrochloric acid, a substance was formed which reduced Fehling's solution. The content of nitrogen of the ash-free albuminoid was found to be 14·2 per cent., consequently this albuminoid must be totally different from the casein and albumin in milk. As this substance has been found in butter made from absolutely fresh cream, it cannot have been formed from the casein in the

cream by an alteration brought about during the ripening process by the action of micro-organisms. The albuminoid in question differs from casein not only in its insolubility in weak alkaline solutions and in dilute acetic acid (both of which dissolve casein readily), but also in its chemical composition, and by the fact of its yielding, when heated with dilute mineral acids, a substance which reduces Fehling's solution. That the reduction of the copper solution could not be attributed to milk-sugar was proved by the entire absence of the colour reaction with α-naphthol before treatment with dilute hydrochloric acid. The only albuminoid proper which forms a reducing substance on treating with dilute acid is serum-globulin, but it forms considerably less thereof than the albuminoid in question. That group of albuminoids which possesses this property (the so-called "gluco-proteids"—mucin—and several nucleo-proteids) differ in chemical composition from the albuminoid in question, as will be shown hereafter. This albuminoid forms at least between 60 and 63 per cent. of the total albuminoid contained in butter.

The residue calculated above from the difference between the butter-serum and the butter-milk-serum is composed of this new albuminoid. From the composition of the butter-serum and of the residue it can be calculated that this albuminoid forms over 60 per cent. of the total albuminoid contents of the butter-serum, or the same amount as found by direct estimation.

It has been shown that more than one-half of the total quantity of the albuminoids of butter consists of a peculiar albuminoid differing in its chemical properties and its chemical composition from the albuminoids hitherto found in milk, viz., casein, lact-albumin, and globulin. As its proportion in butter is, on the average, 0·45 per cent. by weight, it should be present in the milk in sufficient quantity to be identified. As already mentioned, I expected to find it in some way connected with the fat globules, and therefore attempted to free these from milk-serum by washing. Fresh cream was diluted with four times its volume of water and left for the cream to rise, but to my surprise very little cream rose, even after two days' standing. Fresh cream was therefore mixed with four times its volume of a 33 per cent. solution of cane-sugar, and left in a large separatory funnel. After standing for a day a thick layer of cream had formed, and the sugar solution below it had an opalescent appearance almost like a mixture of skim-milk and water. The sugar solution was allowed to drain away, and the remaining cream was again mixed with four times its volume of a 33 per cent. solution of sugar. The cream rose quickly and completely, and the only slightly opalescent sugar solution could be run off after six hours' standing. The cream was washed four times in this way, and as the sugar solution from the fourth washing was perfectly clear, it was considered that the cream was almost completely free from milk-serum and the albuminoids it contained. In the washed cream there was no sign of butter being formed. Stirred in water, it formed an emulsion which, even under the microscope, could not be distinguished from fresh cream. If the fat globules in milk and cream consist of fat only, and are kept from coalescing by the peculiar consistency of the milk-serum, one would expect to see them adhere and form grains of butter when the milk-serum has been washed away. That the fat globules consist of something besides fat is also proved by the following experiment: The washed cream was shaken up with an equal volume of ether, when

only a small portion of the fat solution separated; the cream, however, changed into a gelatinous mass, which collected in the upper part of the vessel, and constituted about one-half of the volume of the mixture. On the addition of a few drops of acetic acid, and again shaking the solution, all the fat dissolved, and under the clear solution of the fat there remained a somewhat opalescent aqueous solution, containing a gelatinous precipitate in considerable amount. Just the same phenomena were observed on shaking the cream with benzene instead of with ether.

The attempts to wash the fat globules with water, which had proved unsuccessful, were repeated with more success by using a hand-separator ("Alpha-Baby"). Ten litres of fresh milk were separated by this machine, the cream mixed with 8 litres of water, and the mixture separated again; and in this way the fat globules were washed four or five times. It was found that at each separation the quantity of cream obtained, and its concentration, varied according to the temperature of the water used. The best result was obtained with water at 35° C. The cream obtained at each separation contained considerably less fat than the cream from the previous separation. In some of these experiments the cream was analysed after each washing in order to be able to calculate, from the composition of the cream and from the quantity of water which had been used, how much serum there would be left in the cream. It was found that after four washings the cream ought to be nearly devoid of milk-serum, for the calculation showed that there would be only 0·003 per cent. of albuminoids derived from the milk-serum present in it, or 0·02 parts to each 100 parts of fat. But the analysis of the cream revealed the presence of 0·184 per cent. of albuminoids, or 1·30 parts per 100 parts of fat; that is, sixty-five times as much as that derived from the milk-serum. Four washings were therefore considered sufficient to render the fat globules as free from milk-serum as could be effected by washing. I have made nine experiments with washing the cream either by water in a separator, or by means of sugar solution in a separatory funnel, and always found in the washed cream a large quantity of albuminoids, but most when the washing was done with sugar solution. As a considerable amount of the albuminoid is separated from the cream when this is washed in a cream-separator, I conclude that a certain proportion of the albuminoids is found in such a state of connection with the fat globules that it cannot be totally removed even by a thorough washing with water. In no case was there any formation of butter to be seen, and the fat could not be extracted by simply shaking with ether or benzene; this converted the cream into a gelatinous mass, in which the fat globules could be seen under the microscope apparently in an unaltered condition. By the addition of acetic acid and renewed shaking, the mixture would separate into a clear solution of fat and an opalescent liquid containing a slimy substance, which could be separated with difficulty by filtration. To obtain this substance, the following procedure is advisable: Shake the washed cream with an equal volume of strong alcohol, then add twice as much ether as the alcohol used, and a proportion of benzol. After thorough shaking, the clear fat solution will gather on the top, and underneath a tolerably clear alcoholic solution will be found, in which there is a gelatinous precipitate of albuminoid which can easily be separated by filtration. Washed with strong alcohol, and afterwards with ether, and dried in the air at the ordinary

temperature, it forms a loose, fine, hygroscopic powder of a grayish-white colour. The albuminoid prepared in this way has exactly the same properties as the albuminoid found in butter. It is insoluble in dilute ammonia, acetic acid, or hydrochloric acid; it swells considerably, without dissolving, in weak solutions of the alkalies. It is only partly soluble in dilute potassium or sodium hydrate. It gives the reactions peculiar to albuminoids, and, when heated with dilute hydrochloric acid, yields a substance which reduces Fehling's solution. The amount of copper reduced by 100 parts of the dry ash-free albuminoid is 6·5 parts. The dried and ash-free albuminoid contains 14·76 per cent. of nitrogen and 2·2 per cent. of sulphur. For comparison I give the proportions of nitrogen and sulphur found in the other fairly well-defined albuminoids:

	Nitrogen.	Sulphur.
Serum globulin, from blood of a horse	15·85	1·11
Serum albumin ,, ,, ,, ...	16·04	1·80
Fibrin	16·91	1·10
Albumin, from egg	15·25	1·80
Albumin, from cow's milk	15·77	1·73
Casein ,, ,, ...	15·70	0·80
Mucin, from salivary gland	12·32	0·84
New albuminoid from washed cream	14·76	2·20

It will be seen that this new albuminoid contains 1 or 2 per cent. less nitrogen than the albuminoids proper, and 2½ per cent. more nitrogen than mucin from the salivary gland; also that its content of sulphur is larger than that of the other albuminoids, from which it likewise differs in its insolubility in caustic alkalies and dilute acids. It is therefore claimed as a new and hitherto unknown albuminoid.

What is the connection between this albuminoid and the fat globules? I thought from the first that the albuminoid might form a membrane around the fat globules, and I succeeded in staining the washed fat globules with the aqueous solutions of different colours, and the fat globules remained stained even after the removal of the excess of staining liquid by thorough washing. It is necessary to employ a stain which does not coagulate the albuminoid; for instance, an ammoniacal aqueous solution of picrocarmine. Under the microscope it was found that the fat globules themselves were not coloured, but were surrounded by a stained envelope which had the same colour as the stain used. This goes to show that the albuminoid forms a membrane around the globules; it also explains (1) why the fat globules in the washed cream do not adhere together to form butter; (2) why ether does not extract the fat from the washed cream; and (3) why such cream is no easier to churn than ordinary cream; but that (4) when churned the butter is formed just in the same way as when normal cream is churned. These facts, therefore, prove that this albuminoid, which adheres so tenaciously to the fat globules that it cannot be separated by washing, forms a *mucoid membrane** around each globule.

To find the amount of *mucoid substance* surrounding the fat globules in cow's milk, I assume that all, or nearly all, of this substance is left when the cream is washed with a strong sugar solution, and that washing with water removes a con-

* By the term membrane is not meant a solid film or skin, but merely a layer, a semi-fluid, viscous envelope.

siderable part of it. In the washed cream I found 0·363 parts of nitrogen to each 100 parts of fat. The albuminoid in the membrane contains 14·76 per cent. of nitrogen; therefore 100 parts of fat will correspond to 2·459 parts of albuminoid.* The amount of water and ash in the mucoid membrane is calculated from the analysis of butter and butter-milk from the same churning, in the way explained in the beginning of this paper. From thirteen different churnings of absolutely fresh cream the percentage composition of the mucoid substance in the butter was found to be:

	Mucoid Substance in Butter from Fresh Cream.
Albuminoid	6·42
Ash	1·03
Water	92·55†
Total	100·00

It is probable that the mucoid membrane of the fat globules is not altered in composition by churning at the ordinary temperature. The composition given above can therefore be taken as the correct composition of the mucoid membrane at the ordinary temperature. Having found to each 100 parts of fat in the washed cream 2·459 parts of dry albuminoid free from ash, the amount of mucoid substance of the above composition corresponding to 100 parts of fat is calculated to be 38·4 parts. The proportion between fat and membrane in the milk-globules is therefore as 100 : 38, or the globules consist of 72·5 per cent. of fat and 27·5 per cent. of mucoid membrane. According to my determinations, the specific gravity of the milk-fat at 15° C. is 0·9335, and that of the mucoid substance of the above composition is 1·0228. The proportion between the volume of fat and the volume of mucoid membrane around the fat globules is, therefore $\frac{100}{0{\cdot}9335} \div \frac{38}{1{\cdot}0228} = 2{\cdot}883$. If the radius of the globules with the membrane is called ϕ, and the radius of the fat globules proper is called r, we have:

$$\frac{r^3}{\phi^3 - r^3} = 2{\cdot}883; \text{ or,}$$
$$\phi = 1{\cdot}104r.$$

The thickness of the membrane $(\phi - r)$ is equal to 0·104 r, or about one-tenth of the radius of the fat globule. The specific gravity of the globule with the mucoid membrane is 0·9565, or appreciably higher than the specific gravity of the butter-fat.

The results of these investigations as to the structure of the fat globules in cow's milk enable us to explain several facts which have hitherto been somewhat inexplicable. It has already been mentioned that it is impossible to extract the whole of the fat from the milk on shaking out with ether, for the simple reason that the mucoid membranes prevent the ether from coming in contact with the fat of the milk

* It will be remembered that by washing with water only 1·30 parts of albuminoids were left in an experiment referred to above.

† It must be distinctly understood that this composition refers only to the mucoid in butter churned from fresh cream at the ordinary temperature. At raised temperatures water is given off.

globules. It has further been mentioned that the globules in washed cream, on being shaken with ether, form a voluminous gelatinous mass, no solution of the fat taking place, for the fat globules remain apparently unaltered in the jelly. This gelatinous mass is formed by the swelling of the mucoid membranes, which are able to absorb ether in a large amount. The mucoid substance surrounding the fat globules absorbs readily ether or benzene, and forms with these a perfectly clear jelly, and it is impossible to perceive small quantities of this swollen mucoid substance in the fat solution. This is of some importance in connection with several methods for estimating the amount of fat in milk.

In the *volumetric* process of Soxhlet the fat is extracted by shaking the milk with a certain amount of potassium hydrate and ether, and estimating the specific gravity of the ethereal solution of fat by means of a special apparatus. It is evident that the value of this method depends upon whether the fat is completely extracted from the milk, and whether the ethereal solution contains nothing but fat. Experience has shown that in some cases it is impossible to get the fat extracted completely from the milk, as a jelly is formed which collects on the top of the mixture, while very little clear fat solution is formed. At other times the method of Soxhlet yields too high a result, and this is evidently due to the circumstance that the fat solution contains some of the swollen mucoid substance, which raises its specific gravity. The same observations apply to the method described by Röse, in which the milk is shaken with ether and petroleum ether after the addition of a certain amount of ammonia, the fat solution being evaporated in a small tared flask, and the dry fat weighed. As the mucoid substance swells considerably under the influence of ammonia, it is very likely that the fat solution obtained by Röse's method always contains some mucoid substance. In experiments in my own laboratory, estimations of fat in milk gave in nearly every case a higher result by Röse's method than by that of extraction after complete drying with kaolin powder. On an average of 500 estimations, 0·04 per cent. more fat was found by Röse's method. In estimating the fat in butter-milk by Röse's method, a still greater discrepancy was found. From the average of the analyses of 82 samples of butter-milk, 0·15 per cent. more fat was found by Röse's method, the limits being 0·11 and 0·18. In the fat extracted by Röse's method a nitrogenous substance was proved to be present. This difference in the results of analysing milk and butter-milk by Röse's method can be shown to be in relation to the amount of mucoid substance in the milk and butter-milk. During the process of churning about three-quarters of the membrane is removed from the globules and left in the butter-milk. While, therefore, fresh milk contains about 1·2 per cent. of mucoid substance (containing about 6 per cent. of albuminoid), butter-milk contains 5 per cent. of mucoid substance, or four times as much as fresh milk; and the excess of fat found by Röse's method was just four times as great when analysing butter-milk as when analysing fresh milk. To extract the milk-fat alone by means of ether or petroleum ether, it is necessary to completely dry the mucoid membrane, as is done when analysing milk by Adams' and several other methods. Even where the milk is treated with strong sulphuric acid before separating, as in the processes of Babcock, Lindstrom, and Gerber, the fat is not pure. The fat, when cooled down until it has solidified and examined under the microscope, is found to

contain minute drops of water, similar to those found in butter. These drops are formed by mucoid substance which has not been separated from the fat.

The membranes around the fat globules prevent them from adhering. To make them adhere—to become butter—the membranes must be for the greater part removed, as is done by churning; but even after the fat globules have been united to form butter, it is likely that each globule is still surrounded by an extremely thin membrane, because many of the globules can again be separated by simply squeezing the butter to a very thin layer. In the edge of such a layer the microscope reveals, especially with dark stage illumination, a number of fat globules separated from the margin of the butter layer, which swim about in an isolated condition in the water that is squeezed out of the butter. The greater part of the membranes is removed during the churning, and when they have been sufficiently reduced, the fat globules adhere together and form small butter-grains with the remaining part of the membranes. These latter are enclosed by the globules, and when examined under the microscope in a thin layer of butter have the appearance of very minute drops of water. In this way the numerous very minute drops of water found in butter are formed; they consist, in fact, not of water, but of the watery mucoid substance. As the churning proceeds, the small butter-grains join together to form larger grains, thereby enclosing particles of butter-milk, which can be seen in the butter as larger drops. The larger particles of butter-milk may be removed by working the butter, but the microscopically small drops, partly formed by the mucoid substance enclosed between the fat globules, cannot be removed by any amount of working the butter. These small drops form an essential constituent of butter, and give it that characteristic appearance, consistency, flavour, and taste, which distinguish it from pure butter-fat. About one-half of the amount of water present in butter is derived from the amount of mucoid substance it contains, which, on the average, is present to the extent of 7 per cent. by weight. The peculiar structure of butter can be seen when a lump of butter the size of a pin's head is gently pressed between the slide and cover-glass to a thin layer without squeezing any of the aqueous portion out of it. Examined under a lower magnification of about 100 diameters, by ordinary illumination with central light, and with a suitable diaphragm, large liquid drops will be seen, and, besides these, a countless number of small spherules, varying in size from mere points to large drops (Fig. A in the plate opposite page 207). In the usual explanation of this microscopical appearance, the numerous very small spheres are regarded as fat globules. But this is not correct; all the spherules seen in a layer of butter when examined in this way are, without exception, liquid drops; the fat globules are absolutely invisible with this kind of illumination. If the layer of butter is submitted to further pressure, whereby the larger water-drops are squeezed out, its thickness can be reduced to about the one-hundredth of a millimetre or less. When this is examined under a magnifying power of about 500 diameters, and with ordinary central illumination, a large number of spherules, varying greatly in size and having a dark edge, will be observed; these are all separated from one another, leaving some vacant places (see Figs. B and C). They all evidently consist of the same substance, and, as many of them are much too large to be fat globules, and as they are all separated, none of them can possibly be fat globules. If the illumination is changed to dark-

ground illumination, the similarity between these spherules and fat globules disappears, and they are found to be water-drops, with a bright reflecting surface (see Figs. D and E). Their aqueous nature is also proved by the fact that many of them contain micro-organisms moving briskly about, and this is only possible in an aqueous liquid. Further, the drops are colored by aqueous solutions of coloring matters, but they remain uncolored when a thin layer of butter is treated with osmic acid.

It is not impossible, however, to see the fat globules in a thin layer of butter. By ordinary central illumination nothing but the liquid drops can be seen (Fig. C), but by dark-ground illumination it is possible, in a very thin layer, to see the fat globules as faint circles, very different in appearance from the luminous drops (Fig. D). The thinner the layer, the more distinctly can the fat globules be seen, and near the edge of an extremely thin layer of butter, with dark-ground illumination, they sometimes present an appearance like pebbles on the seashore (Fig. F, where only a few blurred drops are seen, the many faint circles being all fat globules). A comparison between the two Figs. E and F in the plate is very instructive. They are both taken under the same magnifying power (550 diameter), with the same form of illumination, and represent thin layers of butter. In E nothing is seen but liquid drops, evidently of the same nature as the larger drops seen in Fig. D, while in F hardly anything but fat globules.

If butter is melted by being placed in boiling water, the butter-fat does not collect as a clear fatty layer, but a cream-like layer is formed, in which the microscope reveals the same structure as in the original butter. When butter is melted, a white precipitate forms, which consists of the mucoid membranes, the butter-milk, and salt. If the fat is decanted, the precipitate, after being washed with ether, is seen, under the microscope, to consist of a countless number of microscopic watery drops. Butter, therefore, is a conglomerate of fat globules interspersed with a countless number of very minute liquid drops, of which the smallest and most numerous are formed by the mucoid substance originally coating the fat globules.

A comparison of Figs. D and E, both showing the liquid drops in a thin layer of butter with the same power (550 diameter), will show how various the size and number of these drops may be in different kinds or qualities of butter. I have made a very close study of this subject, and have found that in the best clear waxy butter the number of drops in a cubic millimetre is between three and four millions. In a kind of butter, which it is not desirable to make, being generally bitter and of an opaque or "thick" appearance, the number is on the average thirteen millions. This kind of butter is sometimes found as light streaks or patches in a clear waxy yellow butter. Fig. D shows the structure of the clear waxy butter, Fig. E of the "thick" butter. Some butter is apt to give off brine. This is not necessarily a proof that it contains a large amount of water, but I have found that in such butter some very large drops are generally present (Fig. D). These are removed when the butter is carefully worked, but no amount of working will remove the very small drops. The "thick" butter may sometimes contain as much as 18 per cent. of water in small drops. This water cannot be removed, and the butter appears dry, while a "clear" butter, containing less than 14 per cent. of water, some of which is present as large drops (as in Fig. D), may appear wet and give off brine.

I have found that this different structure of butter—the difference in the size and number of these liquid drops—is caused by changes in the mucoid substance, brought about by the action of special micro-organisms during the ripening of the cream. Some bacteria which cause milk to turn bitter often make the butter "thick," *i.e.*, give it a large content of small liquid drops.

RESUMÉ.

The fat globules in milk are coated with a mucoid substance forming a membrane around each globule. These membranes or semifluid envelopes are retained when the fat globules are washed free from milk-serum. The membranes can be stained and seen under the microscope. The mucoid substance of the membranes is found also in butter as minute liquid drops, and forms over 60 per cent. of the total albuminoid content of butter. It can be proved by a simple calculation from the composition of butter-serum and butter-milk-serum that butter-serum contains an aqueous albuminoid. The albuminoid in question differs from the albuminoids hitherto known.

Butter is a conglomerate of the fat globules of milk, interspersed with numerous minute liquid drops, of which the smallest consist of mucoid substance, the largest of butter-milk. The structure of the butter and the number of liquid drops it contains is partly dependent on the kind of micro-organisms present during the ripening of the cream.

PHOTOMICROGRAPHS OF THIN LAYERS OF BUTTER. BY PROF. V. STORCH.

Power: Fig. A × 93 diameter; Figs. B to F × 550.
Figs. A, B, and C, by central illumination.
Figs. D, E, and F, by dark-ground illumination.

FIG. A.—Some large drops of butter-milk are seen. All round bodies down to the smallest specks are drops of butter-milk and mucoid substance. Thickness, 0·022 mm.

FIG. B.—Liquid drops in butter, the larger drops have been squeezed out. Thickness, about 0·01 mm.

FIG. C.—Liquid drops in a "clear" butter, which gives off brine. Thickness, 0·01 mm.

FIG. D.—The same object as in C, with dark-ground illumination. Some fat globules are seen in the dark spaces between the luminous water-drops.

FIG. E.—Liquid drops in "thick" butter. Thickness, 0·008 mm.

FIG. F.—Fat globules in the thin edge of a very thin layer of butter.

DISCUSSION.

The PRESIDENT having invited discussion,

Mr. RICHMOND said that, owing to the courtesy of Mr. Faber, he had had the advantage of reading through Professor Storch's paper. He had also been performing some experiments, though he was grieved to say that, on account of ill-health, he had not been able to make these experiments as extensive as he could have wished

them to be. On certain points he was able to confirm what Professor Storch had said. He had succeeded in separating the substance described by a slight modification of the method given in the paper. He had taken cream, and washed it with cane-sugar solution until all the milk-serum was washed out. Treatment with alcohol, ether, and benzene produced a substance agreeing in its properties with the substance described. He had also taken butter-milk, and passed it through a separator, obtaining a large deposit. He had not been able to estimate the quantity of this deposit, nor to make an extended examination of it, but it seemed to correspond in its properties with the substance described. Microscopical examination showed that the substance obtained from butter-milk was not in a state of absolute purity. It contained small quantities of vegetable matter (probably derived from the dust of the air) and cells of the udder, which were always present in the deposit found on the inside of the drum of a separator. It also contained a substance having somewhat the appearance of membranes which had been burst, and consisting of partially globoid forms, which appeared to have undergone considerable rough treatment. Innumerable micro-organisms were present in these globules. It could hardly be expected that this substance would agree in all its properties with that described by Professor Storch, owing to the presence of the micro-organisms, which would probably cause a certain amount of change. There were certain points on which he could hardly agree with Professor Storch. If around the fat globule there was a membrane the proportion of which was 38·5 to 100 of fat, it might be expected that cream containing 50 or 60 per cent. of fat would contain a large quantity of this membrane. For instance, cream containing 50 per cent. of fat might be expected to contain about 19 per cent. of the membrane, leaving 31 per cent. of milk-serum. He had therefore thought that by estimating the milk-sugar and proteids in cream, one should get conclusive evidence as to its presence or absence. He had accordingly made a few analyses of cream, a typical one of which was as follows:

Water	39·37
Fat	56·09
Milk-sugar	2·28
Proteids	1·57

Assuming that all except the fat had the same composition as the separated milk obtained at the same time (neglecting the small quantity of fat contained by the latter), he had calculated that it should contain 2·23 per cent. of milk-sugar and 1·55 per cent. of proteids; whereas if Professor Storch's theory were correct, the figures should be about half those amounts. He had found in the case of other samples of cream that the estimated milk-sugar agreed with that calculated from the composition either of the milk or of the separated milk obtained at the same time. The analysis given above was made on the actual sample from which the substance was prepared, so that it must have been present in the sample; but no evidence was given by these figures that it was present in the quantity indicated by Professor Storch, or that the membrane was composed of an albuminoid having the composition stated in the paper. He thought that the evidence advanced by Professor Storch as to the presence of a membrane was not altogether conclusive. The two points relied on by Professor Storch were, firstly, the staining round the fat globules;

and, secondly, their behaviour with ether. It was quite possible to explain these points without assuming the presence of a membrane. If the physical properties of very small globules were considered, it would be seen that the pressure on the surfaces of these globules must be large, and that there must be practically a condensed layer of liquid around them. It seemed to him quite reasonable to suppose that if a stain got into this layer it would not be easily washed out, even though the layer might not necessarily be solid or semi-solid. It also seemed to him that a mixture of small globules of fat with water must be considered as a mixture of two liquids which were not soluble one in the other, separated by a semi-permeable membrane. It should be pointed out that no material membrane need exist; the surface between water and air was almost a perfect semi-permeable membrane, yet no actual membrane was present. The quantity of ether dissolved in the fat was proportional to the quantity dissolved in the water, and to the difference between the maximum solubility of ether in water and in fat. The fat in milk was almost wholly in a solid condition, a condition by no means favourable for dissolving ether; and therefore it seemed quite possible to explain the phenomena observed by Professor Storch when cream was treated with ether, without assuming the presence of a membrane. With regard to Professor Storch's further arguments based on the evidence furnished by the difference between Storch's own method and that of Röse, it need only be pointed out that butter-milk differed in many respects from milk to show how purely circumstantial this evidence was. The appearance of water-globules in the fat separated in the Babcock and other processes when cooled was no argument as to the presence of a membrane; the known solubility of water in hot fat had apparently been overlooked. In conclusion, his opinion was that Professor Storch had established the presence of a new albuminoid in milk, but that the view that he adopted as to its forming a membrane round the globules appeared to be insufficiently supported by the evidence obtained and in contradiction to some of the known facts. He might throw out a suggestion that Professor Storch's albuminoid might be the protoplasm of the cells in which the milk was secreted.

Mr. HEHNER said that the question which this paper revived was one which had seemed to be practically decided in favour of the non-existence of a coating on the fat globules. No doubt very many phenomena connected with the physical properties of milk were more readily explicable if the fat globules were assumed to be coated, but he must say for himself that he was not at all convinced that the fat globules were really coated. The substance described was a very extraordinary substance, differing from any albuminoid known. He would have liked to see actual microscopical representations of the isolated substance; being, as he understood, quite insoluble in most reagents, it ought to retain its characteristics more or less when isolated. He would like to know whether the substance was acted upon by gastric juice, and could be dissolved in this way from the fat globules. Being an albuminoid, it would probably be peptonized, and in that case the fat globules would run together at once without any mechanical treatment if it were really only the presence of an albuminoid substance which prevented their cohesion, instead of the physical causes to which it was attributed by those who contended that the fat globules became connected. He would also suggest that the production of a considerable quantity of Fehling-reducing

substance by hydrochloric acid might be due to the cellulose which would undoubtedly be present, seeing that there would be numerous micro-organisms present containing cellulose, which when acted upon by hydrochloric acid should yield sugar.

Mr. A. C. CHAPMAN remarked that it was well known that certain albuminoids possessed the property of yielding, on boiling with hydrochloric acid, a substance reducing Fehling's solution. He had himself found that such albuminoids existed in yeast.

Mr. ALLEN said it was a well-known fact that bodies of the mucin class had a constitution allied to that of the glucosides, being compounds of a proteid with animal gum, which latter body yields a reducing unfermentable sugar by boiling with dilute sulphuric acid.

Mr. FABER said it was gratifying to find that Mr. Richmond had succeeded in preparing the substance in question. The most important point seemed to be the actual existence of the body. Mr. Richmond had found that it did exist, but had failed to find it in so large a quantity as Professor Storch. In trying to find it, however, he had used a method slightly different from that used by Professor Storch. Professor Storch had tried to produce the albuminoid from very thick cream, but had found that this method did not answer. He had concluded, differently from Mr. Richmond, that his failure to find it in the thick cream was due to the fact that it had been separated from the fat. Not being a perfectly solid body, it was not at all unlikely that during the process of separation it was removed from the fat globules. Its specific gravity was appreciably higher than 1, and that of the butter-fat being less than 1, it was not at all unlikely that during the treatment in the separator these two semi-fluid bodies should separate. It was to be pointed out that the membrane was not, as Mr. Richmond seemed to consider, a solid membrane. It was a semi-fluid, and the difference between a condensed layer of something else and the semi-fluid mucoid substance was therefore very small, and the possibility of explaining the phenomenon in a different way was, he thought, hardly sufficient to completely discount Professor Storch's explanation. Mr. Hehner was not convinced of the existence of this peculiar substance, or, at any rate, of its presence as a membrane, and asked if it was not possible to ocularly prove its existence. When the cream was churned and the mucoid substance broken away from the fat globules, some of it remained enclosed with the fat globules, forming small mucoid drops. These drops retained their shape. If butter were melted at a low temperature, a precipitate was formed under the clear butter-fat, and if this precipitate were rinsed with ether or benzene and examined under the microscope it would be found to consist of these watery or mucoid drops, which retained their shape, and did not run together, as would have been the case in an aqueous solution of an albuminoid. The question as to whether a reducing substance could be formed from the cellulose surrounding the micro-organisms in the cream was one to which, he regretted to say, he felt unable to reply. Assuming, however, that the micro-organisms were actually surrounded by cellulose, it would seem that if their number was such that the cellulose coating them could reduce 6½ parts of copper per 100 of fat, it would be the easiest thing in the world to see them, and he could hardly imagine that Professor Storch would have failed to notice them. That reducing substances were formed from other

albuminoids on boiling with hydrochloric acid was of course well known to Professor Storch, and was duly mentioned in the paper. Of the albuminoids proper, serum globulin gave off a reducing substance, though in smaller quantity than the body under consideration; and similar reducing substances were formed in considerable quantities from compounds of the mucin group.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Reagents distinguishing between Raw and Boiled Milk. R. Dupouy. (*Bull. de la Soc. Pharm. Bordeaux*, March, 1897; through *Jour. Pharm. Chim.*, 1897, 397, 398.)—*Guaiacol.*—One c.c. of a 1 per cent. aqueous solution is added to an equal volume of the milk, and then one drop of ordinary commercial hydrogen dioxide. An immediate yellow colour is produced in the case of raw milk, while with boiled milk the mixture remains colorless.

Hydroquinone.—One c.c. of a freshly-prepared 10 per cent. aqueous solution, mixed with 3 c.c. of raw milk and fifteen drops of commercial hydrogen dioxide, gives an immediate rose coloration, and the mixture, after standing for three or four minutes, deposits green crystals of quinhydrone, $C_6H_4O_2 \cdot C_6H_4(OH)_2$.

Pyrocatechin.—One c.c. of an aqueous 10 per cent. solution, mixed with an equal volume of raw milk, produces, after the addition of a drop of hydrogen dioxide, a yellowish-brown colour.

α-Naphthol.—An aqueous solution, mixed with raw milk and a drop of hydrogen dioxide, gives a violet-blue colour. β-Naphthol treated in the same way produces no colour. Hence this reaction distinguishes between the two naphthols.

Paraphenylene diamine.—Several centigrammes are dissolved in 1 c.c. of water, and to the cooled solution an equal volume of milk and one drop of hydrogen dioxide are added. If the milk is raw, a very dark violet colour is produced. This reaction is very sensitive, and can be used with watered and skimmed milks, which, with the preceding reagents, give the colorations, but with less intensity than normal milk (see also ANALYST, this vol., p. 104). C. A. M.

On the Albuminoids of Cow's Milk. K. Storch. (*Monatshef. Chem.*, 1897, xviii., 244-281.)—The author claims that his experiments confirm Hammarsten's conclusion that there is only one kind of casein present in cow's milk. On saturating milk with sodium sulphate, magnesium sulphate, or sodium chloride, this casein is not precipitated unchanged, but is decomposed into two bodies of similar composition, one of which is precipitated. The casein can be precipitated in an unaltered form by means of acetic acid, and it is possible that simultaneous saturation with two of the three above-named salts might also cause it to separate without decomposition.

C. A. M.

On the Cause of the Coagulation of Heated Milk. B. Bardach. (*Monatshef. Chem.*, 1897, xviii., 199-216.)—The author's investigations have led him to the conclusion that the view of Cazeneuve and Haddon that the coagulation of heated milk is due solely to the action of the acids produced by the oxidation of lactose is incorrect. Preliminary experiments showed that the times and temperatures required for the complete coagulation of fresh milk were: At 100°, about twelve hours; 110°, five hours; 120°, one and a half hours; 130°, one hour; 140°, twenty minutes; 150°, three minutes. The partial separation of albuminoids which occurred on heating milk for several hours at a little below 100° was regarded by the author as quite distinct from coagulation proper. Throughout the subsequent experiments the time and temperature adopted were one hour and 130° respectively, and the milk was heated in an autoclave to avoid frothing.

Fresh milk coagulated at this temperature, and the clear serum, when distilled, yielded as the result of many determinations not more than 0·003 gramme of formic acid per 100 c.c. On adding 3 c.c. of 20 per cent. sulphuric acid to the coagulated milk, the amount of formic acid increased to 0·03 gramme. A subsequent determination of the volatile acid by distilling fresh milk with the same proportion of sulphuric acid gave 0·004 gramme. Hence the difference between this result and the preceding one is ascribed to the volatile acids liberated from combination by heating milk at 130°. This amount of acid is too small to produce coagulation in the cold, for which an acidity of 0·13 per cent. (calculated as acetic acid) was required (Hammarsten, 0·075 to 0·1 per cent.). As regards the combined action of heat and acid, fresh milk, boiled with increasing small amounts of acetic acid, first showed signs of coagulation with 0·055 per cent.; but coagulation was not complete until the percentage reached 0·07—an amount considerably in excess of that produced by heating fresh milk at 130°. Therefore the possibility of the volatile acid being the sole cause of coagulation was out of the question.

A 5 per cent. aqueous solution of lactose heated for an hour at 130° still showed a neutral reaction; but on heating the solution with 0·5 per cent. of hydrogen disodium phosphate at 100° or 150° the liquid became acid. Equal volumes of fresh milk and an aqueous solution of lactose containing hydrogen disodium phosphate, and previously heated at 130°, were then mixed, but there was no alteration in the milk, even when heated on the water-bath for a short time, or boiled once. Hence neither the volatile nor the total acids produced by the oxidation of lactose can be taken as the exclusive cause of coagulation.

The behaviour of solutions of pure casein was next studied. Eight grammes were dissolved in 80 c.c. of water containing 0·8 gramme of hydrogen disodium phosphate, and the solution heated for an hour at 130°. A partial coagulation occurred, but a further deposit could be obtained from the filtrate on the addition of acetic acid. In a solution of half the strength coagulation was retarded, and in very dilute solution was altogether absent. A solution of casein in dilute sodium hydrate subsequently neutralized with hydrochloric acid behaved in a similar manner, showing only incipient coagulation. But a solution of 4 grammes of casein in 110 c.c. of water containing 0·4 gramme of hydrogen disodium phosphate, mixed with an equal volume of 10 per cent. lactose solution, completely coagulated.

A similar solution of casein heated for an hour at 130° gave, as before, incipient coagulation. The coagulum was filtered off, and the filtrate mixed with an equal volume of lactose solution containing hydrogen disodium phosphate, and previously heated at 130°. On now boiling the mixed solution, the remaining casein was precipitated, and the coagulum and filtrate appeared in every respect like those obtained with milk. From these facts, the author concludes that the coagulation of milk on heating is due to the alteration of the casein by heat into such a state that it can be precipitated by the small amount of acid derived from the lactose, which is otherwise incapable of affecting it. C. A. M.

Estimation of Fat in Separated Cream. M. Weibull. (*Chem. Zeit.*, 1897, xxi., 333.)—This process is based on the fact which had been previously indicated by Richmond, that the ratio of water to solids-not-fat is the same in separated cream as in milk. This ratio for the cows usually bred in Mid and North Germany, and in South Sweden he takes at 8·7 ; and his formula for calculating the fat is $F = 1{\cdot}1\,T - 9{\cdot}5$. A number of analyses of sweet and sour cream are appended, showing a mean difference of 0·5 per cent. (maximum 0·9) between the amounts of fat obtained by extraction and by calculation ; and as he lays down the principle that for the commercial examination of cream a process is sufficiently exact if it gives results within 1 per cent. (or at the most 0·5 per cent.) of the truth, he holds that the method is perfectly suited for ordinary purposes. In the case of cream adulterated with water, the process causes the sample to be returned somewhat below its actual value—a point rather in its favour. Creams obtained by the old method of skimming do not yield quite such concordant results ; but of twenty-five specimens only two gave differences of 2 per cent. A lengthy table calculated from the above formula is also included in the paper. F. H. L.

Identification of Genuine Butter, and a Method for distinguishing between Different Fats. A. von Asboth. (*Chem. Zeit.*, 1897, xxi., 312.)—For the examination of butter the author determines in the usual manner the foreign ingredients—water, casein, and salt—the melting-point, and the free acids ; but he obtains the Köttstorfer, Reichert, and Hehner numbers in a different way. His process depends on the fact that the lead salts of the soluble fatty acids are also soluble in water, while those of the insoluble acids are equally insoluble. 2·5 grammes of the sample are heated with 25 c.c. of semi-normal alcoholic potash, and the excess of alkali is titrated with *acetic acid* of equivalent strength to determine the saponification number. The residual liquid is then washed into a 300 c.c. stoppered cylinder containing 150 c.c. of water and 30 c.c. of a 10 per cent. solution of lead acetate, and the whole is well shaken until the precipitate adheres together and the liquid has become clear. It is next thrown on a filter of thick strong linen, and both the cylinder and precipitate washed with cold water. The lead salts of the insoluble acids are freed from moisture by squeezing them thoroughly, removed from the cloth, and put back into the cylinder. 200 c.c. of ether are added, and the mixture agitated till the solid mass is completely broken up. It is rinsed into a 250 c.c. oil burette,

excess of 1 : 4 HCl introduced, and shaken until the ethereal layer becomes clear. The acid is then run off, and the ether washed with water till neutral. The volume of the liquid is read, 50 c.c. are evaporated and dried to constant weight, and another 50 c.c. evaporated, dissolved in 50 c.c. of alcohol, and titrated with potash. The Hehner number is derived from the weight of the dry residue; while the figure obtained on titration, deducted from the saponification number, gives the Reichert number. The lead precipitate does not adhere to the filter-cloth, but may be easily and completely removed by the fingers or a knife; and the whole process is exact, free from manipulative difficulties, and can be carried out—except the drying of the acids—in an hour.

The author's method for distinguishing between different fats is based on an attempt to identify each variety by the proportion of oleic acid it contains. Three grammes of the sample are saponified in 50 c.c. of alcohol and 1 or 2 grammes of caustic potash. Phenolphthalein is added, and the solution neutralized with acetic acid. It is then treated with lead acetate as above, and the insoluble lead soaps collected on the linen filter. The cylinder is drained from the water, the precipitate and 150 c.c. of ether put in, shaken up, and allowed to rest over-night. A funnel and a thick filter-paper large enough to hold the solution and the washings are placed in the oil burette, moistened with ether, the contents of the cylinder thrown thereon, and covered with a dial-glass. The insoluble matter is washed three times with ether—using not more than 100 c.c. altogether—in order to make certain that the whole of the lead oleate is dissolved. The filtrate in the burette is acidified with HCl, shaken up, and washed as before. The total volume of the ethereal liquid is read off, 50 c.c. are evaporated in a beaker on the water-bath, taken up in alcohol, and titrated with decinormal acid. The amount of alkali used multiplied by 0·0282 gives the oleic acid in the ether, whence may be found the quantity existing in the fat. Examined in this manner, ten different samples of butter gave 33·72 to 37·40 (mean 34); several margarine butters, 45·48 to 46·0; oleomargarines, 42·61; baker's fats, 52·73 to 53·37; six lards, 56·91 to 58·08; six goose fats, 64·97 to 67·29; one mutton tallow, 25·44; four beef tallows, 33·03 to 33·95; and two "market fats," 47·76 to 48·69 per cent. of oleic acid respectively. It will be seen that the figures for each separate substance agree closely, except in the case of butter itself (and here the variation is not serious); and the values of all the other fats are very different, with the sole exception of beef tallow, which, however, may be readily distinguished from genuine butter by its difference in consistency and melting-point.

The author holds that butter may be identified by determination of the melting-point, saponification, Hehner, and Reichert numbers; but when it is a question of what or how much foreign fat has been added, the new process, in conjunction with a qualitative examination, is distinctly preferable to any other.

F. H. L.

Properties of Oil of Egg. **M. Kitt.** (*Chem. Zeit.*, 1897, xxi., 303.)—The oil was prepared by extracting with ether the hard-boiled and dried yolks of the (hens') eggs, evaporating the solvent, and removing the lecithine and other suspended matter by filtration through a hot funnel. Forty eggs gave 682 grammes of dry yolk, con-

taining 131 grammes of pure oil, or 19 per cent. It has an orange-yellow colour, is partially solid at ordinary temperatures, gives the Hager-Salkowski's reaction for cholesterin, and yields a solid elaidin. Its constants are as follows:

Oil.		Fatty Acids.	
Specific gravity at 15° ...	0·9144	Melting-point	36-39° C.
Acid number...	1·2	Saponification number (mean)	194·9
Saponification number (mean)	190·2	Iodine number (mean) ...	73·7
Ether number	189·0	Acetylated acid number ...	189·7
Iodine number	72·1	Acetylated sapon. number...	201·6
Hehner's number	95·16	Acetyl number	11·9
Reichert-Meissl number ...	0·4	Mean molecular weight ...	285·0
Glycerin, per cent.	10·4		
Lecithine, per cent.	0·2		
Cholesterin, per cent. ...	1·5		

The lecithine was determined by fusing the fat with potash and nitre, estimating the phosphoric acid in the residue with molybdate, and multiplying the amount found by 11·366. Using Benedikt's formulæ for the calculation of the fatty acids, these become:

Oleic acid	81·8 per cent.
Palmitic acid	9·6 ,,
Oxy- (? stearic) acid	6·4 ,,
Stearic acid	0·6 ,,
Cholesterin	1·6 ,,
	100·0

The oleic acid in the oil itself is therefore 81·3 per cent., or, calculated from the iodine absorption of the fat, 83·6 per cent.

F. H. L.

The Detection of Arachis in Chocolate. A. Bilteryst. (*Bull. de l'Ass. belge*, 1897, x., 447-452.)—According to the author, roasted earthnuts are frequently mixed with cocoa in the manufacture of chocolate, especially in Spain. In such cases a microscopical examination of the chocolate freed from fat and sugar will detect arachis starch, which has characteristic voluminous granules which can readily be measured. A portion of the sample (free from fat and sugar) should also be examined after treatment for twenty-four hours with a mixture of 50 grammes of chloral hydrate and 40 grammes of water. This often enables one to detect the characteristic cellular structure of the earthnut.

The results of the microscopical examination may be corroborated by an examination of the fat and determination of the albuminoid matters. The fat is extracted with carbon tetrachloride, and the refractometer reading taken. When the chocolate has been mixed with earthnuts useful indications may thus be obtained, but when earthnut-cake has been employed it is not possible to draw any conclusion.

The following results obtained by the author show to what extent a determination of the albuminoid substances by Kjeldahl's method indicates an admixture:

	Albuminoid substances Per Cent.
Pure chocolate	9·10
Earthnuts	28·18
Pure cocoa	17·57
Earthnut-cake	46·90
Pure chocolate + $\frac{1}{10}$ earthnuts	12·53
Pure cocoa + $\frac{1}{10}$ earthnut-cake	21·18
Pure chocolate + $\frac{1}{10}$ earthnut-cake	15·70

C. A. M.

The Composition of Chestnuts. M. Balland. (*Jour. Pharm. Chim.*, 1897, v., 525-527.)—In France chestnuts form a considerable item in the food of the people. In 1894, 2,963,845 cwt. were gathered, most of which must have been consumed in the country, since the exportations only slightly exceed the importations. In 1895 the amount imported (chiefly from Italy) was 5,963,273 kilos, as against 8,860,772 kilos exported. Of this latter quantity 5,922,018 kilos were sent to England, and nearly a million kilos to Algiers and Tunis.

The mean weight of the French chestnut was found by the author to be 18·60 grammes, while those from Naples and the Pyrenees were larger. The weight of the shelled nut was from 72 to 84 per cent. of the total weight. The following was the percentage composition of the shelled nuts:

		Water.	Nitrogenous substances.	Fat.	Sugars and Starches.	Cellulose.	Ash.	Acidity.
Minimum	normal	52·80	2·01	·0·45	31·54	0·74	0·57	0·059
	dried	0·00	4·45	1·17	82·17	1·76	1·24	0·164
Maximum	normal	62·60	4·31	1·73	40·74	1·36	1·22	
	dried	0·00	11·05	3·74	88·61	3·29	3·06	

The ash was not fusible like that of wheat; it contained less phosphates, but more chlorides and sulphates. It was usually more or less green, owing to the presence of manganese.

Roasted chestnuts as sold in the streets of Paris still contained 40 per cent. of water, while those cooked for the table by boiling in water contained 72 per cent.

C. A. M.

Detection of Artificial Coloring-matter in Sausages. H. Bremer. (*Forsch. Ber.*, 1897, iv., 45-48.)—The author has frequently met with cases in which the artificial coloring-matter could be detected microscopically in the fibre, but could not be extracted by any of the usual solvents, such as alcohol, amyl alcohol, or a mixture of glycerin and alcohol. In such cases a mixture of equal parts of glycerin and water, as recommended by Klinger and Bujard, is the best solvent. The finely-divided sausage is heated for several hours on the water-bath with two volumes of this mixture (slightly acidified), the yellow solution freed from fat and filtered, and the coloring-matter precipitated as lake by the addition of alum and ammonia. On placing the test-tube before the spectroscope, the absorption-lines of carmine lake lying between *b* and D may then be identified. Since the acid solution of the sausage coloring-matter is yellow, whilst carmine lake gives a red solution with hydrochloric,

nitric, and tartaric acids, it is suggested that the carmine is present in some other form than lake, possibly combining with the preservative to form a compound insoluble in alcohol.

In one instance in the author's experience a cervelat sausage thus colored had all the appearance of good meat when cut, but on further examination was found to be quite unfit for food, the acidity number of its fat being 76·0. C. A. M.

Estimation of Potassium Bitartrate in Wine. L. Magnier de la Source. (*Ann. de Chimie Analyt.*, ii., 101-103.)—To increase the accuracy of the evaporation method, which, though admittedly defective, is still generally employed, the author proposes the following modifications :

1. Ten c.c. of the wine are left to evaporate spontaneously in a basin placed in a desiccator over sulphuric acid, the operation requiring about three days for completion. Meanwhile a solution of potassium bitartrate (1 gramme per litre, the water containing 10 to 12 per cent. of alcohol) is prepared and supersaturated with potassium sulphate. By the aid of 10 c.c. of this solution, the dry residue of the wine is all dissolved, except the potassium bitartrate and sulphate contained therein, and after washing these crystals with the same solution (preventing as far as possible their escape from the basin on to the filter) they are dissolved in hot water, the filter being also washed with boiling water to dissolve any bitartrate thereon, and the resulting solution titrated with lime or baryta water, standardized to saturate not more than 0·005 gramme of bitartrate per 1 c.c. in presence of phenolphthalein.

The advantage presented by the solvent employed over the ordinary saturated solution of bitartrate is that with a small proportion of alcohol it contains only 0·3 gramme of bitartrate per litre, thus minimizing the effect of the errors due to evaporation on the filter, and the acidity of the liquid impregnating the latter.

2. One and a half grammes of potassium sulphate are added to 100 c.c. of wine, the liquid being rapidly concentrated to 15 c.c. on the water-bath, and left to crystallize for forty-eight hours in a cool place. The mother liquor is then decanted, and the crystals and filter washed with the same solution as in the first method, the titration being performed in a similar manner but with a stronger baryta-water (1 c.c. = 0·025 gramme of bitartrate), which increases the precision of the end-point.

The mother liquor, being saturated with potassium sulphate, cannot dissolve more than 0·4 gramme of bitartrate per litre (*i.e.*, 0·06 gramme per 15 c.c.), so that the error due to this cause is minimized.

The method is inapplicable to wines containing any notable quantity of ethyl-tartaric acid, or those wherein the initial proportion of potash does not exceed the amount required to convert the tartaric acid present into bitartrate. The latter case is of rare occurrence in ordinary wines. C. S.

Rapid Method of Detecting Lead Chromate in Papers used for Wrapping Eatables. J. Wolff. (*Ann. de Chimie Analyt.*, ii., p. 105.)—Chocolate, bonbons, etc., are frequently wrapped in paper coloured with lead chromate. To detect this

substance a strip of the paper about 5 c.c. square is moistened with 90° alcohol, and, the excess being poured off, a few drops of nitric acid are spread on the surface of the paper, which turns green from the production of chromium sesquioxide, aldehyde being evolved. The treated paper is washed with 10 to 15 c.c. of water, and this tested with a 10 per cent. solution of potassium iodide. If lead be present, a precipitate of iodide will be formed—provided the excess of nitric acid is not too great—whereas zinc gives no precipitate.

The method is also applicable for papers colored green by lead chromate and Prussian blue. The evolution of aldehyde, detected by its odour, proves the presence of chromium; lead is tested for as above, and the Prussian blue by the ordinary reagents. C. S.

The Presence of Starch and Strontium Sulphate in Opium. L. F. Kebler and C. H. La Wall. (*Amer. Jour. Pharm.*, 1897, lxix., 244-250.)—During the past two years the author has frequently found wheat starch in specimens of opium, varying in amount from a trace to 8 per cent. The adulteration is most frequently met with in Persian opium, and as this is exported by way of Trebizonde to Constantinople, and is there worked up to imitate Asia Minor opium, the admixture is probably made during the process.

The starch may be determined microscopically or chemically. In the former case 1 gramme of the opium is dried, triturated in a mortar with 2 c.c. of alcohol, and mixed with 8 c.c. of simple syrup. The starch granules are then counted in several drops of this with the aid of an ocular micrometer, and the average noted. A syrupy mixture of the same starch as that contained in the opium (say 1 per cent.) is prepared, and the number of granules in a drop of this determined in the same way. When by dilution or by making a more concentrated starch preparation a mixture is obtained containing exactly the same number of granules as the syrup from the sample of opium, the percentage of starch in the latter is readily calculated.

In the chemical method 10 grammes of opium are exhausted with cold water, and the residue boiled for fifteen minutes on the water-bath with 200 c.c. of alcohol containing 5 per cent. of potash. The liquid is filtered hot, and the residue washed with hot alcohol, and, after evaporation of all traces of the latter, boiled for three hours under a reflux condenser with 200 c.c. of water and 16 c.c. of hydrochloric acid (specific gravity 1·16). The contents of the flask are cooled, neutralized with sodium carbonate, filtered, and made up to definite volume. The amount of reducing sugars in an aliquot portion of the filtrate is determined gravimetrically or volumetrically, and the result multiplied by 0·9 gives the quantity of starch (including pentosans and other carbohydrates capable of hydrolysis by boiling with hydrochloric acid) in 10 grammes of opium.

Another impurity in opium is strontium sulphate; it can be estimated in the ash. The author considers its presence particularly objectionable, since it causes the percentage of morphine to appear considerably higher than is really the case. It was first noticed about a year ago, and the practice is still continued, some of the samples assayed during the past few months having yielded unusually high results when examined by the United States Pharmacopœia process. C. A. M.

Examination of Codeine Salts. K. Tambach and F. Henke. (*Pharm. Central. H.N.F.*, 1897, xxxviii., 159; through *Chem. Zeit. Rep.*, 1897, 107.)—Codeine itself contains 1 molecule of water of crystallization, and dissolves in 118·35 parts of water at 15° C.; the hydrochloride contains 1 H_2O, and dissolves in 25·88; the phosphate contains $1\frac{1}{2}$ H_2O, and dissolves in 3·2; and the sulphate 5 H_2O, and dissolves in 33·3 parts of water. The officinal test that the base or the phosphate should dissolve in strong sulphuric acid without colour must be carried out as follows: 0·1 gramme of the phosphate or 0·07 of the alkaloid is gradually added to 10 c.c. of sulphuric acid absolutely free from nitric or nitrous acids, and well stirred up. The pink colour which is first produced disappears in one or two minutes, and the liquid must then remain colourless. The presence of narcotine gives a greenish-yellow, afterwards an orange solution; with 0·1 per cent. the colour is reddish-violet. More than 2 per cent. of papaverine also yields a red-violet liquid. Morphine is indicated if a blue colour is produced when 10 c.c. of a solution of potassium ferricyanide, containing one drop of ferric chloride, are mixed with 1 c.c. of normal nitric acid in which 0·01 gramme of codeine has been dissolved. F. H. L.

The Chemical Valuation of Antipyrin. C. Kippenberger. (*Zeit. anal. Chem.*, 1896, xxxv., 659-677.)—When an aqueous solution of antipyrin, whether containing acid or not, is mixed with a solution of an iodine salt containing free iodine, a compound having the composition $C_{11}H_{12}N_2O.HI.I_2$ is precipitated. The reaction is quantitative when there is a sufficient excess of iodine, and when some mineral acid is present, can be used for the separation of antipyrin from phenacetin, sulphonal, aniline salts, and acetanilide.

A solution of antipyrin (as concentrated as possible) is shaken with a slight excess of iodine solution, prepared by mixing the ordinary $\frac{N}{10}$ or $\frac{N}{20}$ iodine solution with hydriodic acid in such proportion that 100 c.c. of $\frac{N}{20}$ iodine solution contain 4 c.c. of hydriodic acid of specific gravity 1·7 (= 52 per cent. HI). After from two to four minutes the liquid is filtered through asbestos from the precipitate, and an aliquot portion of the filtrate titrated with standard thiosulphate. From the amount of iodine consumed, the quantity of antipyrin can be calculated, 21·3 c.c of $\frac{N}{10}$ iodine solution corresponding to 0·1 gramme of antipyrin. The presence of hydriodic acid and its salts causes the antipyrin periodide compound to slightly dissolve, so that when absolutely accurate results are required the iodine solution should be standardized on an antipyrin solution of known strength.

Aniline salts also combine with iodine, but the compound is dissolved by acid. When they are present, however, it is well to filter off the antipyrin precipitate as rapidly as possible. C. A. M.

Analysis and Composition of Liquorice Extract. G. Py. (*Journ. Pharm. Chim.*, 1897, 280-284.)—The presence of gelatin in liquorice may be detected by the precipitate obtained with tannin, phosphomolybdic acid, picric acid, etc., in an

aqueous solution of the portion insoluble in 75 per cent. of alcohol. (See abstract, this volume, p. 192.)

If only an examination for gelatin is required, the original sample may be tested in the following manner: About 5 grammes of the extract are dissolved in 50 c.c. of hot water, allowed to cool, and the solution saturated with ammonium sulphate to precipitate the glycyrrhizin and gelatin (if present). The precipitate is washed with a saturated solution of ammonium sulphate, and then with alcohol (75 to 80 per cent.). This dissolves the glycyrrhizin, and any precipitate left can be dissolved in water and tested for gelatin by the usual reactions.

Gum may be looked for in the liquid which has been tested for gelatin (*i.e.*, aqueous solution of substances insoluble in 75 per cent. alcohol). (1) It gives a white precipitate when tested with a mixture of three drops of a solution of sulphate of copper (1 : 10) and 10 c.c. of potash (45° Bé). (2) It gives a precipitate with ferric chloride to which an equivalent of calcium carbonate has been added. These tests give negative results with pure liquorice extract.

A microscopical examination will detect the presence of starch and lamp-black, which are frequently found in liquorice pastilles.

The following table gives the results of the analyses made by the author:

	Pure Extract.	Pharmaceutical Extracts.		Commercial Extracts.

Gelatin	—	—	+	—	—	—	..	+	+	+	+	+	+	+	+	+	—	—
Microscopical examination.	Liquorice starch.	Liquorice and Potato starch.	Farina and Liquorice starch.	Liquorice small amount.	Rice.	Foreign starches.	Farina large proportions.	Small amount of rice.		Farina.	Liquorice starch granules, occasionally granular albuminoid matter.						Considerable amount of foreign starches.	

The pure liquorice extract was prepared in the laboratory, while the others were representatives of the ten brands most commonly occurring in the market. With the exception of number seven, which consisted of a mixture of starch, sugar, glycyrrhizin, and gum, the extracts, whether containing gelatin or not, only showed a marked difference in the amount of glycyrrhizin. In the author's opinion all extracts containing less than 10 per cent. of that constituent must be regarded as derived from spent liquorice.

ORGANIC ANALYSIS.

Determination of Aldehyde in Ether. M. Francois. (*Jour. Pharm. Chim.*, 1897, v., 521-525.)—The proposed method consists in the application of Schiff's reagent as a colorimetric quantitative reagent. The colour produced by the sample is compared with those yielded by ether containing known quantities of aldehyde.

C. A. M.

On the Estimation of Formaldehyde. G. Romijn. (*Zeit. anal. Chem.*, 1897, xxxvi., 18-24.)—The methods of Legler, Brochet, and Cambier were studied, and the results obtained with them compared with those given by two new methods described by the author. For this purpose four aqueous solutions were prepared containing in 500 c.c.: (1) 2·075 grammes of formalin; (2) 2·075 grammes of formalin + 1·3 gramme of acetaldehyde; (3) 2·075 grammes of formalin + 0·355 gramme of acetone; (4) 2·075 grammes of formalin + 1 gramme of benzaldehyde.

Iodometric Method.—Ten c.c. of the aldehyde solution are mixed with 25 c.c. of decinormal iodine solution, and sodium hydrate added drop by drop until the liquid becomes clear yellow. After ten minutes hydrochloric acid is added to liberate the uncombined iodine, which is then titrated back with standard thiosulphate. Two atoms of iodine are equivalent to 1 molecule of formaldehyde. The results obtained with the first solution showed that the formalin used contained (1) 37·38 and (2) 37·40 per cent. of formaldehyde.

With the second solution a certain amount of iodoform was produced, and the results were too low. With the third solution the acetone was entirely converted to iodoform, and in the fourth solution the benzaldehyde was partially oxidized. Hence this method, though suitable for the valuation of pure formaldehyde, does not give correct results in the presence of other aldehydes.

Potassium Cyanide Method.—This is based on the fact that formaldehyde combines with potassium cyanide. The addition product reduces silver nitrate in the cold. But if the silver nitrate be acidified with nitric acid before the addition of the aldehyde cyanide mixture, no precipitate results if the aldehyde in the latter be in excess. If, on the other hand, the potassium cyanide is in excess, one molecule of potassium cyanide is left in combination with one molecule of the formaldehyde, while the excess precipitates silver cyanide from the silver nitrate solution.

Ten c.c. of decinormal silver nitrate, acidified with nitric acid, are mixed with 10 c.c. of potassium cyanide solution (prepared by dissolving 3·1 grammes of the 96 per cent. salt in 500 c.c.), the whole diluted to 500 c.c., filtered, and 25 c.c. of the filtrate titrated by Volhard's method. The difference between this blank result and that obtained by titrating the filtrate after the addition of the aldehyde solution gives the amount of standard sulpho-cyanide corresponding to the silver not precipitated by the excess of potassium cyanide. From this the amount of formaldehyde can be calculated. With solution 1 the results showed 37·39 and 37·67 per cent. of formaldehyde in the formalin. With solution 2, if the titration was made immediately after shaking, only the formaldehyde had combined, but if left for some time the acetaldehyde also began to combine, and erroneous results were obtained. Solutions 3 and 4 gave correct results, even after standing for thirty minutes.

Hydroxylamine Method (Brochet and Cambier, *Comp. Rend.*, cxx., 449).—This gave satisfactory results with pure formaldehyde, but quite irregular figures with the other three solutions.

Legler's Method (Ber., xvi., 1335).—The four solutions were made more concentrated, in order to lessen the difficulty of observing the end reaction. In each case the correct amount of formaldehyde was found, but the author does not consider the method so accurate as the others. C. A. M.

On the Low Iodine Number of Linseed-Cake Oil. G. Fassbender and J. Kern. (*Zeit. angew. Chem.*, 1897, 331, 332.)—Ketel and Antusch (ANALYST, xxi., 299) came to the conclusion that the low iodine value of oil extracted from linseed-cake was due to the presence of cotton-seed oil, and not to foreign seeds in the original linseed. The authors show that this conclusion may be incorrect, for on pressing in the cold linseed, containing a small percentage of the usual foreign seeds, a separation of the oils takes place, the linseed-oil flowing away, whilst the heavier crucifer oils remain behind; so that linseed-cake prepared from impure linseed contains a much more impure linseed-oil than does the original seed. This is shown by the iodine values given in the following table:

Oil from	Pure Linseed.	Impure Linseed, containing 5·3 per cent. Crucifer Seeds.
I. Cold-pressed. Per cent. of oil brought from 37 to about 25	180·5	180·5
II. Pressed at 70°. Per cent. of oil brought from 25 to 12	180·3	175·3
III. Extracted. From 12 per cent. to 0 ...	179·9	162·5

C. A. M.

Krüger and Wulff's Process for estimating Alloxuric Substances (Xanthine Bases) in Urine. Huppert (*Zeits. Physiol. Chem.*, 1897, xxii., 556); also **Salkowski** (*D. Med. Wochenschr.*, 1897, xxiv., 14; through *Chem. Zeit. Rep.*, 1897, 105.)—Both authors state that this process is not reliable, for the mixture of copper sulphate and sodium bisulphite used by Krüger and Wulff yields a precipitate containing too much nitrogen when it is calculated into alloxuric substances, this being due to the fact that the reagent throws down not only xanthine bases and uric acid, but also albumin, secondary albumoses, and thiocyanogen (according to Huppert) when these bodies are present in the urine. F. H. L.

INORGANIC ANALYSIS.

The Determination of Sulphur in Pyrites and Blende. M. Noaillon. (*Bull. de l'Ass. belge*, 1897, x., 443-444.)—A weighed quantity (1·5 gramme) of the sample is oxidized with 10 c.c. of nitric acid and 10 c.c. of a 30 per cent. solution of sodium chlorate, the object of the latter being to provide a base to combine with the free sulphuric acid liberated during the reaction. The flask is placed in water to keep the contents cool, and the oxidation is complete in thirty minutes, without separation of sulphur, and almost without liberation of gas.

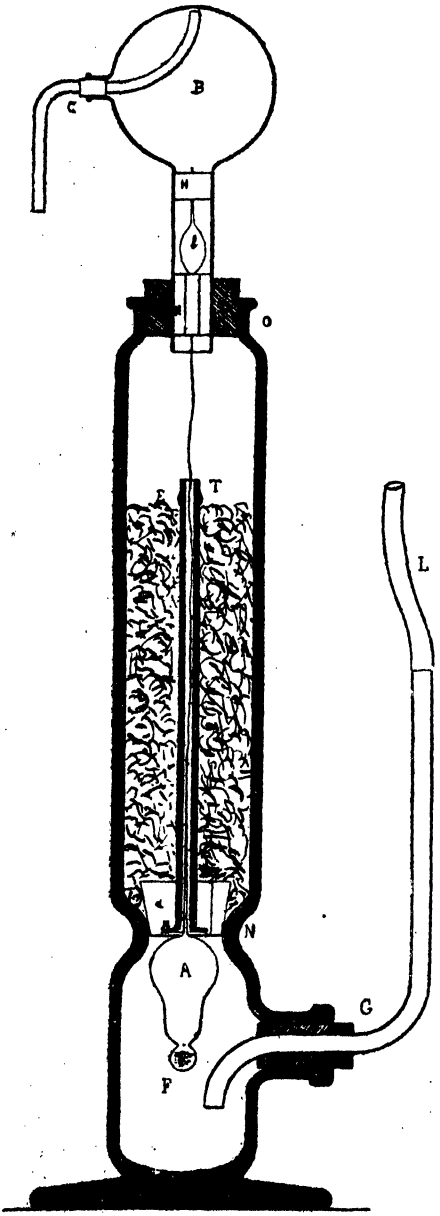
The nitric acid is then expelled by evaporating twice at 200° with hydrochloric acid. The residue is dissolved in a little hydrochloric acid, the solution diluted, and the iron precipitated with ammonia.

The cooled liquid is made up to 600 c.c., and filtered, without washing the precipitate. 200 c.c. of the clear filtrate (=0·50 gramme pyrites) are boiled to expel excess of ammonia, acidified, and the sulphuric acid determined in the usual manner by precipitation with barium chloride.

The influence of the volume of precipitated ferric hydrate is quite negligible in a solution of 600 c.c.

Although, if the blende be pure, there is no liberation of acid, as in the case of pyrites, it is always advisable to introduce a base as above, since commercial blendes frequently contain more or less pyrites. C. A. M.

The Use of Acetylene in Quantitative Analysis. H. G. Söderbaum. (*Ber.*, 1897, xxx., 902-904.)—Acetylene precipitates copper from ammoniacal solutions of the latter as black copper-acetylide. The reaction is complete, and no trace of copper can be detected in the filtrate after the acetylide has been filtered off. The following mode of carrying out the estimation of copper by means of acetylide is recommended: The salt is dissolved in 100 to 200 times its weight of water contained in an Erlenmeyer flask, made ammoniacal and gently warmed on the water-bath. Acetylene is then passed through to saturation. Although the precipitation is complete in the cold, it is better to warm the solution, in order to hasten the reaction and to make the precipitate more flocculent. After filtering off and washing, the acetylide is digested for half an hour with warm dilute nitric acid. The black residue is filtered off, and the filtrate evaporated and gently ignited, when copper oxide is obtained. The filter and residue are separately burned, and the small amount of oxide added to the first quantity of copper oxide. Accurate results can be obtained.



The presence of alkaline salts does not influence the precipitation, whilst it is retarded by ammonium salts.

The Separation of Copper from Zinc.—The presence of zinc salts prevents the precipitation of copper acetylide. If, however, a little sulphurous acid is added to the solution before passing in the acetylene, the copper is thrown down as a reddish-brown precipitate, which gradually becomes black. It may be filtered off and treated as above. The results, as shown by a number of figures given in the paper, are quite reliable. W. P. S.

APPARATUS.

Automatic Generator for Sulphuretted Hydrogen. Crouthière and Désolu. (*Ann. de Chimie Analyt.*, vol. ii. [2], 21-24.)—To prevent the overflow of the generating liquid into the receiver when the pressure of the gas no longer suffices to maintain it in equilibrium, the authors have designed an apparatus with automatic valves. The generator consists of a vertical calcium chloride tube connected with the reservoir of acid by the lower tubulus and attached tubing. A long 8 m.m. bore tube, flanged at its lower end, is passed through a cork fluted at the sides, which rests on the constriction in the generator. This tube serves as a guide for the stem of a hollow glass float loaded with 20 grammes of mercury and placed in the lower part of the generator, the upper part being then charged with ferrous sulphide nearly up to the top of the narrow tube. In the caoutchouc stopper at the mouth of the generator

is fitted a reversed half-litre bulb tube, the neck of which contains a glass bulb drawn out at either end to a point; these ends rest in guide tubes, and pass through corks at the top and bottom of the neck, the lower cork being fluted round the sides. The lower end of this bulb-float is connected with the stem of the lower float by a platinum wire. The bulb is pierced at one side by a tubulus, through which passes a tube leading to the gas-washing apparatus, the tube itself being turned up inside the bulb to prevent splashing over when the reaction is violent. The acid, on being admitted into the generator, rises through the channels in the cork, reacts on the ferrous sulphide, and ascends the tube, as the pressure of gas diminishes, until it reaches the neck of the bulb, where it raises the second float, and by closing the upper tube is prevented from ascending further. The gradual evolution of gas then forces the liquid down once more until the lower float is passed, and this, in descending, draws with it the upper float and re-opens the upper valve, thus relieving the pressure and allowing a fresh quantity of acid liquor to enter from the reservoir (the spent portion falling to the bottom on account of its greater density), the operation being repeated automatically until the acid is exhausted. The mixture of the fresh and spent liquids in the reservoir is effected by adjusting the bulb-tube so that the lower float does not draw the upper one until the liquid has sunk to the level of the feed-tube, whereby the gas bubbles up through the latter into the reservoir for a moment.

In unmounting the apparatus, the lower bulb is floated in liquid so as to release the tension on the wire, which is then unfastened, after removing the inverted bulb-flask, the tube and charge being withdrawn by a running-noose cord, which catches on a bulge at the top of the tube. All the corks are steeped in paraffin to preserve them from the action of the acid, and the reaction of the sulphuretted hydrogen on any free chlorine present prevents the latter from attacking the platinum wire.

C. S.

THE ANALYST.

SEPTEMBER, 1897.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

NOTE ON THE INDIRECT (TABARIE'S) METHOD FOR THE ESTIMATION OF ALCOHOL.

By Norman Leonard, B.Sc., F.I.C., and Harry M. Smith, F.I.C.

(*Read at the Meeting, June* 2, 1897.)

In this well-known process the amount of alcohol in a spirituous liquid is calculated from two data: (1) the specific gravity of the original liquid, (2) the specific gravity of the liquid after removal of alcohol by evaporation and subsequent making up to the original volume with water. In the method as first published the specific gravity of the alcohol evaporated was stated to be found by dividing the specific gravity of the original liquid by that of the de-alcoholized liquid. For some time, however, a difference of opinion has existed as to the proper method of calculation, and, instead of the original "division" formula, a "subtraction" formula has been frequently employed. In the latter case the specific gravity of the alcohol evaporated is obtained by subtracting from the specific gravity of the original liquid the excess over unity of the specific gravity of the de-alcoholized residue. This calculation has been claimed to be both simpler and more in accordance with experimental results than the "division" formula. A few experiments made with a view to decide the relative value of the two methods have been recorded by Allen, Hehner, and Blunt (Analyst, xvi., 221, 223; xvii., 5), but no systematic investigation of the subject appears to have been carried out. The following observations and experiments are put forward in the hope of throwing some light on the matter.

Looking at the matter from the simple theoretical standpoint, apart from any errors involved in the actual working of the process, we have, for comparison, the specific gravities of three liquids:

1. An aqueous solution containing per 100 c.c., say, p. grammes of alcohol and q. grammes of non-volatile dissolved matter. The specific gravity of this "original" liquid we denote by O.

2. A solution containing per 100 c.c. p. grammes of alcohol, but no other dissolved substances. Let the specific gravity of this "distillate" be denoted by D.

3. A solution containing per 100 c.c. q. grammes of dissolved solid matter, but no alcohol. The specific gravity of this "residue" is denoted by R.

According to the division formula $D=\frac{O}{R}$, and by the subtraction formula $D=O-R+1$; the two equations may be written $\frac{1-D}{1}=\frac{R-O}{R}$ and $1-D=R-O$ respectively. Thus the subtraction formula is based on the assumption that the lowering of density due to the presence of alcohol is the same whether dissolved solid matter be present or not. The division formula, on the other hand, assumes that this lowering is proportional to the density of the de-alcoholized liquid. Or, in other words, the subtraction formula assumes that the substances in solution exert their influence on the density of the liquid, irrespective of each other's presence. The division formula, however, implies an expansion increasing in amount both with the amount of alcohol and with the amount of extractives.

It should be observed that the division formula must necessarily give a higher specific gravity, corresponding to a lower percentage of alcohol, than the subtraction formula. For the difference between the two values obtained for D, viz., $\frac{O}{R}$ and $O-R+1$ is $\frac{(R-O)(R-1)}{R}$, and this is always positive. The difference increases both with the amount of alcohol and with the amount of dissolved solids.

In the accompanying table are given the results of a number of experiments which were carried out in the following manner. Mixtures of pure cane-sugar, alcohol of known specific gravity, and water were made, the substances being carefully weighed out in stoppered flasks. After mixing, the solutions were allowed to stand some hours, and the specific gravity determined. The percentage composition by weight and by volume of each solution could now be calculated. The figures are given in the first four columns of the table. Having previously made experiments on the specific gravity of solutions of cane-sugar, we were able to calculate what the specific gravity of each solution would be if deprived of alcohol. This figure is given in column 6. Similarly, from the usual alcohol tables, we found the specific gravity of a liquid containing the alcohol actually present, but devoid of sugar (column 7). Thus, in the first experiment each 100 c.c. of the solution contained 1·950 grammes of sugar and 2·201 c.c. of alcohol. Its specific gravity was 1·0043. The specific gravity of a 2·201 per cent. by volume solution of alcohol is 0·9969, while the specific gravity of a solution of cane-sugar containing 1·950 grammes per 100 c.c. is 1·0076. These are therefore the calculated specific gravities of the "distillate" and of the "residue" respectively. In columns 8 and 9 are given the results of the application of the subtraction formula to the numbers in columns 5 and 6, together with the differences between these results and the numbers in column 7. In columns 10 and 11 are given similar figures for the division formula.

The results of the first series of experiments, in which the sugar amounted throughout to about 2 per cent., show that the division formula gives accurate results for all strengths of alcohol. The subtraction formula, on the other hand, always gives low results, the deviation steadily increasing with the amount of alcohol present.

In the second and third series, with 10 and 27 per cent. of sugar respectively, the same steady increase in the deviation of the subtraction formula is seen, but the division formula is no longer trustworthy.

We are unable to detect any simple relation between the numbers we have obtained, and, taking into consideration the fact that so little is known, except empirically, of the connection between the density and composition of even simple solutions, it is not to be expected that a simple and accurate expression of the facts should be found in the more complicated case of two substances in solution. In the practical application of Tabarie's process, moreover, we are met with further difficulties in the presence of dissolved substances other than sugar and of volatile substances other than alcohol. Of the latter, some—*e.g.*, carbonic acid—may be present in the original liquid, but not in the distillate, thus introducing another source of error, as was pointed out by S. Harvey (ANALYST, xvii., 1).

Since writing the above, our attention has been called to a paper by H. Droop Richmond (*J. Fed. Inst. Brewing*, 1896, ii., 529-535), in which an attempt is made to theoretically demonstrate the validity of the subtraction formula. The reasoning, however, is based upon the assumption that the solution densities of alcohol and of the extractives are the same, whether only one or both substances are present in solution. As we have pointed out above, the subtraction formula does indeed imply that the substances exert their specific influence on the density of the solution, independently of each other's presence; but this supposition is not in accordance with the results of our experiments. The latter show that when solutions of sugar and alcohol are mixed, a slight expansion takes place, the actual density of the mixture being lower than that calculated by the subtraction formula.

Our thanks are due to Dr. Thomas Stevenson for permission to carry out these experiments in his laboratory.

Discussion.

Mr. Hehner thought that the paper had a special value as giving experimental data which would be of use in arriving at a settlement of this question. He did not think that purely theoretical conclusions were of much use in themselves. A very much more extended series of experiments was to be desired, though these of Messrs. Leonard and Smith appeared to strongly favour the division formula.

Mr. A. C. Chapman remarked that, in the case of beer, if one subtracted the present gravity from the extract gravity, a number was obtained which was always slightly lower than the difference between the distillate gravity and unity. Judging from the numbers given by the authors, this did not appear to be the case with the solutions examined by them.

The President said that, as nearly as he could recollect, Mr. Chapman's observations were in accord with the experience of Mr. Harvey, whose work had been referred to in the paper. Despite all the work that was being done in physical chemistry, there was still much to learn about the state of bodies in aqueous solution. The aggregation of molecules and the degree of hydration might be very sensibly affected by dilution with alcohol in directions that might give rise to some of the apparent discrepancies that had been referred to.

NOTE ON THE DETERMINATION OF PROTEIDS BY CHLORINE.

By S. Rideal, D.Sc. Lond., and C. G. Stewart.

(*Read at the Meeting, June* 2, 1897.)

In 1876 one of us, in conjunction with the late Dr. Bernays, made a large number of experiments with the object of determining the presence and amount of gelatin in meat-extracts. In Liebig's original formula, gelatin and fat were intentionally excluded from such meat-extracts; consequently, one of the first questions asked of an analyst in examining a meat-extract was, "Does it contain any gelatin?" Inasmuch as the latter is obtained from the cheaper parts of meat, or from other sources, and gives to the extract a spurious solidity and "strength," it was regarded, and is still considered to be, an undesirable constituent, which under certain circumstances may amount to an adulteration. The determination of gelatin became, therefore, of considerable importance, and at the present time the method based upon its insolubility in ice-cold water has been apparently adopted as the last resource of the analyst. Experiments, in which an attempt was made to utilize the tannin reaction, either by weighing the precipitate, or by adding a slight excess of tannin solution and titrating back with permanganate, gave very unsatisfactory results. Other processes, based upon the use of ferrocyanide and on dialysis, also failed to give any reliable quantitative results.

The reaction with chlorine water in excess was subsequently tried, and the insolubility of the precipitate with this reagent suggested its use as a means of

determination. The precipitate subsides in compact flocks, is easily filtered, and yields a clear filtrate. By weighing the precipitate, after drying at a low temperature, results were obtained with gelatin which were comparable with the tannin process when worked under the most favourable conditions, but much more easily, and with a far better agreement between repeated analyses. The process was not published, but having had a number of meats and meat-extracts to examine last year, we decided to undertake a further investigation into it.

It was found that a current of chlorine precipitated in a weighable form all albuminous substances, that the precipitation was delicate and complete, and that the bases, such as creatine, etc., were not precipitated. The chlorine compound was remarkably stable at ordinary temperatures, but if heated it readily decomposed, becoming nearly black, and rotting the filter-paper. In the precipitation hypochlorous acid seemed to be the principal product. Finally, the following procedure was adopted :

A hundred c.c. of the liquid, containing not more than 0·2 per cent. of proteids, were submitted in a beaker to a steady current of chlorine. The phenomena noticed in every case were similar. The solution remained for a time clear, then it began to froth strongly, the bubbles being encased with a white film, and at this period it should be stirred with the delivery-tube. In a short time the frothing ceases, the precipitate becomes granular and the liquid clear. As soon as the latter shows a marked yellow colour the current of chlorine is stopped. The solutions can be filtered at once, although it is preferable to allow them to stand for some hours, as the precipitate then becomes more compact and more easily filtered. It is collected on a weighed Schleicher and Schüll's hardened filter-paper, 9 cm. diameter, used with a water-pump, washed thoroughly with cold water until all free chlorine is removed, and the paper and its contents drained and allowed to dry, as far as possible, in warm air, the drying being finished *in vacuo* over sulphuric acid. In the earlier experiments the precipitate when nearly free from water was finally dried in a water-bath ; but if the temperature exceeds 70° or 80° C. decomposition ensues, and the results are never so uniform as by drying *in vacuo*. The dried precipitate is of a pale, yellowish-white colour, pulverulent, and quite inodorous. In an earlier experiment to determine the relation of the weight of the chlorine precipitate to that of gelatin, a sample of the white commercial gelatin was dissolved to a 1 per cent. solution, and 25 c.c. of this solution diluted to 100 c.c. were then precipitated with chlorine. The product, dried at 70° to 80° C., weighed 0·213 gramme, so that 1 gramme of the gelatin used yielded 0·852 gramme of chlorine precipitate. As the sample was found to contain 25·53 per cent. of water, it followed that 0·852 gramme of chlorine precipitate was yielded by 0·7447 gramme of anhydrous substance (not ash-free). This determination gave the factor 0·87 for multiplying the weight of the chlorine precipitate in order to convert it into the equivalent of dry commercial gelatin.

To further examine this factor, a solution of " Coignet's Extra Gelatin," of about 9 per cent. strength, as prepared for bacteriological work, but with exclusion of the other nitrogenous matter, was analysed by the several methods. The original material contained 19·27 per cent. water and 2·96 per cent. ash, leaving 77·7 per cent. of organic matter, or approximately 7 per cent. in the solution.

The results of a duplicate analysis were as follows:

	Grammes per 100 c.c. I.	II.
Total nitrogen	1·242	1·246
× 5·5 = gelatin	6·83	6·86
Nitrogen in ammonium sulphate precipitate ...	1·109	—
× 5·5 = ...	6·10	—
Nitrogen in Stutzer precipitate	0·514	0·528
× 5·5	2·83	2·90
Stutzer filtrate precipitate by ammonium sulphate (direct weighing)	4·37	4·27
Total proteid	7·20	7·17
Chlorine precipitate	9·375	9·300
× 0·87	8·19	8·12
× 0·74	6·94	6·88

These results show that the factor 0·87, which was deduced from the first experiment, making no allowance for ash, gives too high a result. Taking the total nitrogen × 5·5 as representing the total proteid present, the factor 0·74 gives the actual relation of the chlorine precipitate to the dry and ash-free proteid in this gelatin solution. We were surprised to find that Stutzer's reagent, made according to the directions of Heaton and Vasey (ANALYST, 1892, p. 29), gave a precipitate with the solution, as the gelatin used appeared to be pure and of the best quality, and was analysed in a perfectly fresh and sterilized condition. This solution was prepared for studying the bacteriolysis of gelatin to be referred to in a subsequent paper.

It seems probable that the Stutzer reagent precipitates a portion of the gelatin, which may be partly hydrolysed in its manufacture. We have, however, noticed from several experiments that the most consistent jellies give the largest precipitate with Stutzer's reagent. The Stutzer precipitate from a gelatin, when decomposed by sulphuretted hydrogen, yields a jelly, so that we are inclined to the belief that it cannot be looked upon as a reliable reagent for differentiating between gelatin and albumose in a solution consisting mainly of gelatin. The following figures, obtained from three gelatins, "somatose," and Witte's peptone, will illustrate this point, and also the mean factor, 0·78, with which it is proposed to multiply the chlorine precipitate to attain the total proteids:

	Nelson's No. 1 Gelatin.	Coignet's Extra Gelatin.	Swiss Gold Label Gelatin.	Somatose.	Witte's Peptone.
Water	18·96	17·85	17·84	7·3	7·62
Ash	4·19	1·5	1·47	1·06	2·46
Total nitrogen	13·8	14·61	14·33	13·72	14·67
× 5·5	75·9	80·35	78·81	—	—
× 6⅓	—	—	—	86·75	92·91
Total organic matter ...	76·85	80·65	80·69	91·64	89·92
Nitrogen in ammonium sulphate precipitate	13·69	13·63	13·92	12·44	10·13
Nitrogen in phospho-tungstic precipitate	13·72	14·00	14·16	12·65	12·65

	Nelson's No. 1 Gelatin.	Coignet's Extra Gelatin.	Swiss Gold Label Gelatin.	Somatose.	Witte's Peptone.
Nitrogen in Stutzer precipitate	4·09	5·91	4·59	6·64	4·52
Chlorine precipitate ...	99·2	103·48	97·8	103·6	92·0
× ·78	77·38	80·60	76·28	80·81	71·76
Nitrogen in phosphotungstic precipitate :					
× 5·5	75·46	77·0	77·88	—	—
× 6·3	—	—	—	79·67	79·67

It will be noticed from the above results that the total nitrogen in the three gelatins gives the factors 5·56, 5·52; 5·63 for conversion into total organic matter present, and these figures are in fair accord with the usual factor 5·5 for gelatin. The gelatin, calculated from either the nitrogen in the ammonium sulphate precipitate or the phosphotungstic acid precipitate, would give slightly lower results, due to either incomplete precipitation or losses in the two processes. The Stutzer reagent (perfectly neutral) gave, as in former experiments, a precipitate with all three gelatins, and duplicates with a fresh reagent confirmed these determinations, but as the second preparation was slightly alkaline the results were somewhat higher.

Although the solutions were of equivalent strength, and the analysis shows that gelatins 2 and 3 had approximately the same amount of water and ash, gelatine 2 gave a very much more consistent jelly than gelatin 3. This discrepancy of physical character manifests itself in the lower Stutzer and chlorine figures in No. 3, while the ammonium sulphate and phosphotungstic results show a tendency in the opposite direction.

In the somatose and peptone, any calculation from the total nitrogen gives results which do not represent the total proteids present. The ammonium sulphate and phosphotungstic acid give very close agreement in the case of somatose, showing the absence of peptone.

The chlorine precipitate figures, when multiplied by 0·78, give results which seem in close accord with the known amount of proteid present in all cases except the peptone. The amount, however, is higher than that given by the ammonium sulphate determination, so that peptone is precipitated by chlorine, but the weight of the precipitate is probably less than that of the other proteids. Assuming 6·3 as the nitrogen equivalent of the proteids in Witte's peptone, and that phosphotungstic acid precipitates all the proteid matter, but none of the bases, we have 79·67 per cent. of total proteids, as against 71·76 per cent. found by chlorine on the basis of the factor 0·78.

The chlorine precipitates from different sources show a remarkable similarity. The amount of nitrogen in a number of them was found by Kjeldahl's process. The results were :

In Precipitates dried finally at 70° *to* 80° *C.*—Meat-extracts (containing albumoses, gelatin, and peptones), three different samples, 13·91, 13·79, and 14·27 per cent. of nitrogen.

In Precipitates dried in a bell-jar over Sulphuric Acid.—Two samples of meat-extract, 12·00 and 12·24. A gelatin, 11·99. Egg-albumen, 12·15. Another gelatin, 12·75.

In Precipitates also dried in vacuo over Sulphuric Acid.—Swiss gold-label

gelatin, 13·88. Nelson's No. I., 13·37. Coignet's extra gelatin, 14·09. Somatose, 13·40. Witte's Peptone, 13·53.

It will be noticed that the average of these five last determinations, 13·65, is exactly three-quarters of the percentage in gelatin, 18·2, on which the factor 5·5 is founded. The nitrogen in the chlorine precipitate multiplied by 7 3 gives in these cases the weight of crude proteid.

The process had been tried on a number of meat-extracts, prepared in the laboratory according to Liebig's method by digesting 1 lb. of meat with 1 pint of water for six hours, heating to coagulate albumen, etc., and filtering. The chlorine precipitates, calculated by the factor first used, 0·87, gave percentages of soluble proteids amounting in the five cases to 1·83, 1·65, 1·92, 1·98, and 1·51, the results agreeing with the detailed analyses in assigning their relative values to the products.

At the time of the inception of the investigation, it was found that bromine also precipitated the proteids; an attempt was therefore made to volumetrically estimate them by adding a known quantity of bromine in excess, and then titrating back with thiosulphate. The method was found to succeed fairly well in solutions of proteids free from bases, but inasmuch as the latter, though not precipitated, absorb much chlorine or bromine, the method was inapplicable to meat-extracts and to most organic fluids.

We are at present studying to produce a weighable precipitate by bromine instead of by chlorine, as the former reagent presents several advantages.

It is doubtful whether phosphotungstic and other precipitants do not also throw down from animal solutions some of the nitrogenous extractive acids and other substances which have not been sufficiently considered; chlorine, on the other hand, seems only to precipitate the proteids.

A careful search through chemical literature, which was made while these experiments were pending, yielded no record of the properties or composition of the chlorine precipitate; it was only incidentally mentioned. But more recently, in going back as far as 1840, it was found that this precipitate had actually been made use of by Mulder as one of the foundations of his protein theory. He called the precipitate "proteinchlorous acid" (*Berzel. Jahresb.*, xix., 734; *J. f. Chem.*, xliv., 489), and stated that there was first formed "chlorite of albumen, which produces sulphide of silver with silver salts, afterwards proteinchlorous acid, the sulphur of which no longer acts on silver (being probably oxidized). The acid is obtained of constant composition by drying at 80° C." He describes its properties in terms which are practically identical with our observations. The following early analyses are recorded:

COMPOSITION OF CHLORINE COMPOUND FROM THE SOURCES MENTIONED.

	MULDER.			VAN LAER.	
	Gelatin.	Albumen.	Fibrin.	Casein.	Hair.
C	46·66 46·25	48·0	48·2	48·48	48·40
N	15·59	14·11			14·09
H	5·90 5·81	6·21	6·16	6·38	6·08
O	23·37				
ClO_3	8·48 8·47	11·44	11·46	12·27	12·61

De Vrij (*Ann. Pharm.*, lxi., 248) and others denied the presence of chlorous acid, and a considerable controversy ensued as to the nature of the compound, although all agreed as to its properties, its constancy, and its insolubility. With the collapse of the protein theory this early work seems to have been forgotten. We will hazard at present no theory as to the constitution of the body, beyond pointing out that the percentage of nitrogen found by the early observers agrees closely with the amount found by us in specimens dried, as directed by Mulder, at 80° C., and that the formation of hypochlorous acid was invariably observed in our experiments.

See also Thenard (*Mem. d'Arcueil*, ii., 38), Mulder (*Bullet. en Neerlande*, 1839, 153), and Berzelius (*Jahresb.*, xix., 729).

Discussion.

Mr. Allen suggested that by making a Kjeldahl determination on the chlorine precipitate, it might be possible to avoid the necessity for weighing the precipitate itself. He was much interested in the references made to the use of bromine. Those who were in the habit of using halogen reagents would certainly use bromine in preference to chlorine whenever it was possible to do so. He thought the authors were to be congratulated on having hit upon what promised to be a very useful method of throwing down proteids. He would like, however, to know exactly what bodies they included in the term "proteids." It was sometimes difficult to know where to draw the line in a definition of this kind. Thus, some chemists excluded peptones from, and others included peptones in, the class of proteids.

Mr. Hehner said he would have liked to see some data as to the application of the method to other albuminoids than gelatin; and also to know if albumin, albumose, and peptone respectively were precipitated, and to what extent.

Mr. Richmond asked why the authors had made use of the particular factor 6·55. Was it obtained as the result of actual determinations of the mixture of proteids in the substance? It seemed to him extremely probable that all the gelatin might not be thrown down. It was shown that the precipitate, dried over sulphuric acid, contained 12 per cent. of nitrogen, and that the weight of this precipitate, multiplied by 0·87, gave the original gelatin. Now, 12 divided by 0·87 gave something under 14, and surely gelatin contained much more nitrogen than that. It might be that the Kjeldahl process was not reliable for a substance containing chlorine in organic combination, as free chlorine might be liberated, and this would act on the ammonia, and, neglecting intermediate products, produce free nitrogen. Nitrogen might be lost in this way. He would like to ask how the ammonium sulphate precipitates were determined, whether by actual weighing, or by determination of the nitrogen; and, if the latter, whether the factor 6·55 was used.

Mr. Bodmer said he understood that this process was intended for the estimation of gelatin, but as far as he could make out only the total proportion of gelatin and albumoses together appeared to be given. The determination of gelatin as such was really the most difficult point in the analysis of meat-extract.

Mr. Bevan inquired whether the nitrogen had been estimated in the filtrate from the chlorine precipitate. If so, this would answer the remark of Mr. Richmond as to whether the whole of the gelatin had been precipitated.

The PRESIDENT said that he had determined the nitrogen in one or two organic compounds containing chlorine or bromine, including potassium parabromochloronitrophenol, and had found no difficulty whatever. He could quite understand that the presence of chlorine might possibly give rise to trouble if it were to act as an oxidizing agent, because the permanganate of potash, which was in earlier times used in the Kjeldahl process, had a tendency to produce low results, owing to oxidation of the ammonia. He thought, however, that if there were any such tendency on the part of chlorine in organic combination, it might be got over by the use of zinc.

Mr. ALLEN said that one atom of chlorine could not combine with more than one atom of hydrogen, and as the number of hydrogen atoms was considerable, he did not think there was much chance of the chlorine acting as an oxidizing agent. Although the question was theoretically a very interesting one, he did not think it likely that it would assume a serious aspect in practice.

Dr. RIDEAL, in reply to Mr. Allen, said that he used the term "proteid" as an equivalent to "albuminoid," as he preferred the former to the latter when speaking of gelatin and gelatin derivatives. He would not venture on a definition, but proteids, he thought, ought not to be dialyzable; this would exclude peptones, which differed from the other proteids chemically, and the value of which as foods was still under discussion.

The following table shows the results obtained by kjeldahling the dry chlorine precipitate, from which it appears that chlorine carried down practically all the proteid nitrogen. There could be no doubt that the precipitation of gelatin and of other proteids by chlorine was complete, the only question being as to the composition of the precipitate.

No.	Description.	Weight of Proteids anhydrous and ash-free.	Weight of Chlorine precipitate.	Ratio of Chlorine precipitates to Proteids.	Kjeldahl Nitrogen in Proteid. In reply to Mr. Richmond, he had given in the paper results calculated to the factor 5·5 for the nitrogen in gelatin, and 6·33 for other proteids. The factor 6·55 was used to show the agreement in the first series of experiments with the nitrogen results. The precipitate, when dried over sulphuric acid, contained from 13·5 to 14 per cent. of nitrogen, whatever its source might be. In precipitating with ammonium sulphate, they had found it best to estimate the nitrogen in the precipitate, as this gave better results than direct weighing. In reply to the President and Mr. Allen, kjeldahling the moist precipitate had not been tried, as they thought that loss of nitrogen might be occasioned. When the precipitate was dry, as shown in the above table, the whole of the nitrogen appeared as ammonia.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Direct Detection of Nitrites in Milk. E. Riegler. (*Pharm. Central-H.*, 1897, xxxviii., 223; through *Chem. Zeit. Rep.*, 1897, 117.)—Normal milk contains neither nitrites nor nitrates. To detect nitrites, 20 c.c. of the sample are shaken with 0·05 gramme of Riegler's reagent (equal parts of naphthionic acid and β-naphthol) and 5 drops of strong sulphuric acid for a minute. One or 2 c.c. of strong ammonia are then added, and the whole again agitated. The existence of 0·001 gramme of N_2O_3 in 100 c.c. of milk produces an intense red colour, and 0·0002 gramme gives a pale rose. F. H. L.

Detection of Sesame Oil in Butter and Margarine colored with Curcuma. M. Hanause. (*Jour. Pharm. Chim.*, 1897, 350-351.)—The red colour given by curcuma with hydrochloric acid often causes uncertainty in the test for sesame oil. Finding that glacial acetic acid either prevents or considerably weakens the action of the acid on curcuma, the author has modified the test in the following manner: The melted butter is mixed with 5 c.c. of glacial acetic acid in a test-tube, which is heated until the acid boils. Three c.c. of hydrochloric acid containing furfurol are then added (see ANALYST, xix., 47, and xxi., 135), the tube well shaken, and allowed to stand. If the butter is free from sesame oil the acid has only a faint rose-violet tint; whereas, when the oil is present, the colour is reddish-violet, and the fatty layer above is a yellowish-rose when hot, and a yellowish-white when cold. If after twenty-four hours the tubes are placed horizontally on white paper, the acid which has acted on the butter not containing sesame oil shows a reddish-brown tint, whilst that in the other tube has a grayish-black shade. These reactions have been obtained with samples of butter and margarine containing 1 per cent. of sesame-oil.

C. A. M.

Preliminary Examination of Cheese. A. Forster and R. Riechelmann. (*Zeit. für öffent. Chemie*, iii., 159.)—In the course of the administration of German law by the police, it frequently happens that cheeses are sent to the analyst in large

batches at a time, and have to be examined as quickly as possible. In accordance with the agreed official methods of Saxony, these samples have first to be subjected to a preliminary examination, consisting, among other things, of the refractometric examination of the fat.

The authors recommend the following plan for the separation of the fat, which they claim possesses advantages over the methods of Henzold and Hefelmann (ANALYST, this vol., p. 159) in requiring but 3 to 5 grammes of cheese, and in being exceedingly quickly carried out. A portion of the cheese is cut up into pieces of the size of matches, and 3 to 5 grammes introduced into the lower and wide part of a Gerber's butyrometer, with both ends open. The lower opening is then closed with a caoutchouc stopper, and 6·5 c.c. of boiling water introduced. After shaking, about 6·5 c.c. of sulphuric acid, of 1·820 to 1·825 specific gravity, as recommended by Gerber, are introduced, and the whole shaken, to effect the solution of the cheese, which is usually complete in about a minute. The butyrometer is then filled up to the top of the graduated tube with hot water, and allowed to rest. The fat soon rises up the tube, but, if required, the separation can be accelerated by centrifuging. A drop of the fat is then removed and placed between the prisms of the refractometer.

The following table shows how small are the differences between the results obtained by the authors' method and the methods of von Raumer and Bremer:

Description of Cheese.	Differences in the Readings of the Refractometer.

H. H. B. S.

The Quantitative Determination of Carbohydrates in Food Stuffs. W. E. Stone. (*Jour. Amer. Chem. Soc.*, 1897, xix., 183-197, and 347-349.)—Most of the analyses of food material fail to give any information about the "nitrogen-free extract," in which are often grouped together several compounds, chiefly of a carbohydrate nature, which differ widely in their chemical and physical properties, and in their physiological action. The carbohydrates in vegetable food stuffs comprise sugars, starch in various modifications, substances closely associated with cellulose and designated as gums, pentosans, hemi-celluloses and oxy-celluloses, and, finally, cellulose itself. Reliable methods for the determination of each of these are already known, but, as a rule, they require the absence of the other substances. The method described by the author is based on the successive treatment of the same sample: (1) With boiling alcohol to remove sugars; (2) with cold water to remove dextrin and

soluble starch; (3) with diastase or malt infusion to remove starch; (4) with dilute boiling hydrochloric acid to convert gums, pentosans, etc., into soluble reducing sugars; (5) with boiling 1·25 per cent. sodium hydroxide, leaving behind the crude fibre.

From 50 to 100 grammes of the finely-powdered material are boiled with 500 c.c. of strong alcohol under a reflux condenser, or extracted with it in a Soxhlet apparatus. The alcoholic solution is filtered, and if it only contains sucrose, the amount of the latter is determined with the polarimeter. When more than one kind of sugar is present the alcohol is evaporated, the residue taken up in water made up to definite volume, and the sugars estimated by titration with Fehling's solution before and after inversion.

The residue from the alcoholic extraction may contain carbohydrates soluble in water, such as dextrin and soluble starch, especially when the materials have been subjected to the action of heat. This residue is therefore treated with 500 c.c. of water, and allowed to stand for eighteen to twenty-four hours with frequent agitation. The aqueous solution is then filtered through a linen filter, and when only dextrinous substances are present, concentrated, inverted, and titrated with Fehling's solution in the usual way. When soluble starch is present, as shown by iodine solution, the aqueous solution is concentrated to 200 c.c., and the total carbohydrates determined in an aliquot part. Another fraction is treated with excess of barium hydroxide, which precipitates the soluble starch, and the dextrin again determined in the filtrate by inversion and titration as before. The difference between this result and the preceding gives the amount of soluble starch in the fraction taken.

The residue from the aqueous extract is air-dried and weighed. Two grammes of it are boiled with 100 c.c. of water for thirty minutes, then cooled to 60° C., and mixed with 10 c.c. of an infusion made by steeping 10 grammes of finely-ground malt in 50 c.c. of water for two or three hours. The mixture is kept for two or three hours at a temperature not exceeding 65° C., and when the starch is completely converted, the solution is passed through a linen filter and the residue well washed with hot water. The filtrate is evaporated to 100 c.c., transferred to a 200 c.c. flask, mixed with 10 c.c. of hydrochloric acid, and kept in the water-bath for an hour. The solution is then neutralized, made up to 200 c.c., and titrated with Fehling's solution, a correction being made for the amount of sugar introduced in the malt-extract.

The residue from the malt extraction is mixed with 100 c.c. of water, and 2 c.c. of strong hydrochloric acid, and boiled under a reflux condenser for an hour. By this means the gums, pentosans, etc., are converted into reducing sugars, which may be regarded as xylose. The solution is filtered, neutralized, made up to 200 c.c., and titrated with Fehling's solution, each c.c. of which requires for complete reduction 0·004617 gramme of xylose. The equivalent of the xylose in xylan originally present may then be calculated according to the proportion :—

$$\underset{\text{Xylose}}{C_5H_{10}O_5} : \underset{\text{Xylan}}{C_5H_8O_4} :: 100 : x.$$

The residue from the hydrochloric acid treatment is boiled under a reflux condenser with 200 c.c. of 1·25 per cent. sodium hydroxide, filtered, washed, dried, weighed, ignited and weighed again, as in the manner prescribed for the estimation of

crude fibre by the Weender process. The substances extracted by the alkali are not hydrolysable to reducing sugars, and do not appear to be of a carbohydrate nature, though they often form a considerable proportion of the nitrogen-free extract.

The following table gives the percentages of different carbohydrates in certain food substances:

	Sucrose.	Invert Sugar.	Dextrin.	Soluble Starch.	Normal Starch.	Pentosans.	Cellulose.

C. A. M.

Determination of Caffeine in Coffee. A. Forster and R. Riechelmann. (*Zeit für öffent. Chemie*, iii., 235.)—The authors traverse the statement of Juckenack and Hilger (ANALYST, this volume, p. 190), that the use of soda in their method for the determination of caffeine vitiates the results. Having made four determinations in the same coffee extract by their method, two with and two without the use of soda, they found:

	With Soda.	Without Soda.
1.	5·21 per cent. caffeine.	5·18 per cent. caffeine.
2.	5·24 ,, ,,	5·24 ,, ,,

The use of soda promotes a clean separation of the aqueous solution from the chloroform, without any intermediate emulsion. H. H. B. S.

Estimation of Caffeine in Kola, Guarana, and Coffee. C. H. La Wall. (*Amer. Jour. Pharm.*, 1897, lxix., 350, 351.)—By this, which closely resembles the Keller process for tea, the use of the Soxhlet apparatus is obviated, and the results obtained in a much shorter space of time. Five grammes of the sample are mixed with 5 c.c. of 10 per cent. ammonia solution, and after being left for thirty minutes the alkaloid is shaken out with chloroform in three successive portions of 20 c.c., emulsification being avoided by adding a little powdered magnesium car-

bonate. The mixed chloroform washings are transferred to a weighed flask, the solvent evaporated, and the residue, consisting of fat and alkaloid, weighed. The fat is then extracted with warm ether, the successive fractions being decanted each time without loss of caffeine, and the residue again dried and weighed. In the case of kola, the ether also removes the theobromine; but this being but a small percentage, may be ignored.

The results thus obtained with kola-nuts showed 1·37 to 1·48 per cent. of caffeine as against 1·39 per cent. by extraction with chloroform in a Soxhlet apparatus. With two samples of guarana the corresponding figures were 4·62 to 4·68 and 4·32 per cent. respectively. C. A. M.

Estimation of Alkaloids in White Hellebore. C. H. La Wall. (*Amer. Jour. Pharm.*, 1897, lxix., 351, 352.)—Keller's assay process was found to give satisfactory results. Ten grammes of white hellebore are mixed with 25 grammes of chloroform, 75 grammes of ether, and 10 grammes of 10 per cent. ammonia solution in a flask, which is well shaken and allowed to stand for six hours or overnight. Five c.c. of 10 per cent. ammonia solution are then added, and after being well shaken, 50 grammes of the clear solution (=5 grammes of white hellebore) are poured off into a separating funnel, and the alkaloid extracted with acidulated water, 3 fractions of 20 c.c. each being used. The aqueous washings are transferred to another funnel, made alkaline with ammonia, and the separated alkaloids shaken out with a mixture of chloroform and ether (3 : 1). This extract is placed in a weighed flask, the solvent evaporated, and the residue dried and weighed.

Five different samples of the commercial drug, in the form in which it is sold for an insecticide, when thus assayed, yielded from 1·12 to 1·15 per cent. of alkaloids, while a sample of the whole drug ground gave 1·75 per cent. The author considers that 1 per cent. would be a fair limit for the minimum yield of alkaloids by this process. C. A. M.

The Estimation of Menthol in Oil of Peppermint. L. F. Kebler. (*Amer. Jour. Pharm.*, 1897, lxix., 189-195.)—Power and Kleber were the first to adapt the acetylation test for fixed oils to the examination of oil of peppermint (*Pharm. Rundschau*, xii., 157), but as their method requires about a day, the author has modified it so that the percentage of menthol can be determined in about three hours.

Estimation of Combined Menthol.—From 10 to 12 grammes of the oil (accurately weighed) are boiled for an hour under a reflux condenser with 12 c.c. of normal alcoholic potash, and the excess of alkali titrated back with standard sulphuric acid, with phenolphthalein as indicator. Each c.c. of alkali consumed corresponds to 0·156 gramme of menthol in the form of esters.

Estimation of Total Menthol.—From 12 to 15 grammes of the oil are boiled for an hour under a reflux condenser with an equal weight of acetic anhydride and 2 grammes of anhydrous sodium acetate. When cool, the mixture is washed twice in a separatory funnel with 150 c.c. of water. After the second washing the aqueous layer is removed, and 50 c.c. of water added, together with a few drops of phenolphthalein solution and sufficient 5 per cent. aqueous potash to just give an alkaline

reaction. More water is then added (about 100 c.c.), the whole contents of the funnel are well shaken, and after the layers have separated, the alkaline aqueous solution is withdrawn. The oily layer is again washed with 150 c.c. of water, and when this has been removed as completely as possible, the acetylated oil is transferred to a boiling-flask, the last portions being washed out with alcohol. From 50 to 60 c.c. of normal alcoholic potash are added, the mixture boiled for an hour under a reflux condenser, and the excess of alkali titrated with normal sulphuric acid. The difference between the amount of menthol found and that obtained in the previous determination gives the amount of free menthol.

The following table gives the results obtained with commercial menthol and with a number of specimens of oil of peppermint, all of which the author believed to be genuine, with the exception of that marked "unknown":

Source.	Specific gravity at 15° C.	Per cent. Menthol as Esters.	Per cent. Free Menthol.	Per cent. Total Menthol.	Number of c.c. distilled from 50 c.c. of Oil between										Residue.

* Degrees Centigrade, uncorrected. † Degrees Centigrade, corrected.

C. A. M.

On Commercial Acacia. J. H. Schroeder. (*Amer. Jour. Pharm.*, 1897, lxix., 195-199.)—The United States Pharmacopœia directs that this gum shall be the product of *Acacia Senegal*, and shall comply with the following tests:

(*a*) It shall be soluble in two parts of water, shall give a gelatinous precipitate with basic lead acetate, ferric chloride, or a concentrated solution of sodium borate, and shall not reduce alkaline cupric tartrate.

(*b*) It shall not be colored blue (starch) or red (dextrin) with iodine solution.

The author has examined fifteen representative samples of powdered gum arabic, and although free from dextrin or starch, they all caused a reduction of Fehling's solution at a temperature below 100° C.

Another test (not official) for dextrin is to add to 6 c.c. of a 20 per cent. solution of the gum 3 c.c. of a solution composed of fifteen drops of a concentrated solution of

potassium ferricyanide, five drops of hydrochloric acid (specific gravity, 1·165), and 60 c.c. of water. When dextrin is present a blue colour is said to be produced in about twenty minutes. The author was unable to obtain satisfactory results with this test, as powdered gum arabic free from dextrin showed the blue colour within fifteen minutes. He suggests that changes may occur during the drying of the gum which account for the reactions with Fehling's solution and the ferricyanide solution.

C. A. M.

The Composition of Orris Root. S. A. Tucker. (*Amer. Jour. Pharm.*, 1897, lxix., 199, 200).—Commercial orris root is the rhizome of *Iris Florentina*, deprived of its cortex and dried in the sun. It has a delicate aroma, and when granulated or powdered is used in the manufacture of perfumes, floral extracts, and tooth powders.

In a specimen of the prepared rhizome examined by the author, 1·34 per cent. of fat and wax was extracted with petroleum spirit, whilst 4·13 per cent. of the total substance was soluble in absolute alcohol. The aqueous extract amounted to 14·02 per cent., including 8·31 per cent. of glucose, 1·27 per cent. of sucrose, and a small amount of substances precipitable by alcohol, but no tannin. The odoriferous principles were soluble in alcohol, but not in water. The total organic matter dissolved by water made alkaline with sodium hydrate was 30·30 per cent., consisting for the most part of albuminous and mucilaginous matters, which were precipitated on adding acetic acid and a large volume of water.

Starch was present to the extent of 16·85 per cent.; the moisture was 8·74 per cent., and the ash 2·12 per cent. The latter contained calcium, magnesium, and potassium as carbonates, chlorides, and phosphates. The cellulose and undetermined substances amounted to 10·37 per cent.

C. A. M.

TOXICOLOGICAL ANALYSIS.

Delicacy of Marmé's Test for Alkaloids. S. Verven. (*Ann. Pharm.*, 1897, xiii., 145; through *Chem. Zeit. Rep.*, 1897, 116.)—The tests were carried out by shaking 5 c.c. of a solution of the alkaloid made slightly acid with sulphuric acid, together with 1 c.c. of a solution containing 5 grammes of cadmium iodide and 10 grammes of potassium iodide in 100 c.c. of water. The figures recorded in the first column represent the maximum dilution at which a faint precipitate could be seen; and in the second the point where no precipitate was obtained, even after several minutes:

Atropine	1,600	1,900
Veratrine	5,400	8,200
Aconitine	13,700	27,400
Brucine	14,600	18,200
Cocaine hydrochloride	16,900	20,800
Cinchonine	18,400	24,600
Strychnine	19,200	32,000
Quinine	32,300	37,700

F. H. L.

Detection of Arsenic in Forensic Work. E. Fricke. (*Chem. Zeit.*, 1897, xxi., 303.)—According to the author, the faint volatile "mirror" which occasionally appears in the reduction-tube of the Berzelius-Marsh apparatus, even when the material under examination is free from arsenic, and every care has been taken in the selection of the reagents, is due to the presence of carbon in the zinc employed. The nascent hydrogen may conceivably attack this carbon, producing compounds which are again split up on reaching the hot part of the tube. Fresenius has noted the formation of a similar mirror consisting of silicon; but as this is non-volatile, it cannot be confused with arsenic.

In order to avoid this possible source of error, and also to simplify the process of detecting arsenic generally, Fricke dissolves in ammonium sulphide the precipitate which is always produced by sulphuretted hydrogen in the original liquid after the organic matter has been destroyed, evaporates the solution to dryness, fuses the residue with soda and nitre, and boils the aqueous extract with sulphuric acid. If on being treated again with sulphuretted hydrogen this solution remains clear, arsenic is absent; but if a yellow precipitate is formed, it may then be submitted to Marsh's test for further corroboration. F. H. L.

ORGANIC ANALYSIS.

Examination of Bees-wax. S. Weinwurm. (*Chem. Zeit.*, 1897, xxi., 519).—The author does not consider that Benedikt and Mangold's modification of Hehner's process (wrongly attributed to Hübl) has any advantages over the original form; for it is more complicated, and the difficulty of completely saponifying a wax, even when adulterated with ceresin or paraffin, has been greatly exaggerated. The latter operation can be effected in a covered flask on the water-bath in half an hour, the alcohol being subsequently evaporated off. Benedikt has referred to the "abnormal" acid number 23 and saponification number 90·6, which give a low Hübl ratio. Genuine samples are often seen with an acid number of 24; and this rises to 25 or 26, when they contain a small amount of stearic acid, which is probably not put in as an adulterant, but arises from the use of artificial combs partly composed of the material in question. On the other hand, the acid number may fall to 17·8, with a saponification number of 92·3, and a ratio of 4·2, whence it follows that the determination of these constants is not sufficient to ensure freedom from sophistication. Moreover, the employment of ceresin, stearin, tallow, etc., singly is rapidly diminishing, the substance commonly added being a mixture of stearic acid, Japan-wax, and ceresin, so proportioned as to give the correct figures. It is customary, also, to test for stearic acid, rosin, and glycerin. The first can be detected if it amounts to 1 per cent., rosin only in somewhat larger quantities, while an equal amount of glycerin cannot possibly occur. Determinations of the melting-point and of the iodine number are quite useless; and if Buisine's method be employed it is requisite to estimate the hydrocarbons, as well as the hydrogen evolved.

Two or 3 per cent. of ceresin or paraffin, or 5 per cent. of rosin, may be discovered qualitatively as below. Five grammes of filtered wax are saponified in 25 c.c. of

seminormal alkali and the alcohol removed, 20 c.c. of glycerin are run in, the whole warmed in the water-bath till solution is effected, and 100 c.c. of boiling water added. Pure wax gives a clear, transparent or translucent solution, through which ordinary printed matter can be read with ease. Five per cent. of ceresin or rosin yields a cloudy liquid, and the print is no longer legible; 8 per cent. of ceresin causes a decided precipitate. If the solution is clear, 3 per cent., or, if it is opaque, 2 per cent. of ceresin is added to another sample of the wax and the saponification repeated, when from the appearance of the soap solution the presence or absence of either impurity may safely be deduced. F. H. L.

Proposals with the Object of Establishing Uniformity of Procedure in Determining the Saponification and Acid Numbers. R. Henriques. (*Zeit für öffent. Chemie*, iii., 236.)—As the absence of uniformity in the procedure of different chemists in determining the saponification and acid numbers has frequently led to differences in results, the author puts forward suggestions, founded upon his own experience, with the object of promoting more general agreement.

Saponification Number.—The quantity of substance to be taken from the determination should be 3 to 4 grammes, and not 1 to 2 grammes, as originally proposed. It is immaterial whether potash or soda be used for the saponification, provided the results are expressed in terms of KHO; but the author prefers soda, as sodium carbonate is very nearly insoluble in alcohol of 95 to 96 per cent. For this reason, the alcoholic solution should, by preference, be made by dissolving the sodium hydrate in alcohol direct, instead of by first dissolving in water and then adding the alcohol.

For warm saponification, 3 to 4 grammes should be placed in a flask fitted with a reflux condenser, and either 25 c.c. $\frac{N}{2}$ alcoholic alkali added or 25 c.c. normal alcoholic alkali and 25 c.c. alcohol. The flask should then be boiled briskly for from half an hour to an hour, and the excess of alkali titrated back with $\frac{N}{2}$ hydrochloric acid.

For the cold saponification of oils and fats, 3 to 4 grammes should be dissolved in 25 c.c. petroleum spirit in the cold, and allowed to stand for twenty-four hours at the ordinary temperature. Waxes should be treated thus: Dissolve by warming in 25 c.c. petroleum benzine (boiling at 100° C.); then add the alkali, and again warm for a few moments to ensure complete solution.

Acid Number.—The quantity taken may be the same as in determining the saponification number, though in certain cases, as, for instance, with lubricating oils, it is better to take as large a quantity as possible—say, 5 to 10 grammes. The author dissolves, as a rule, in petroleum spirit or ethylic ether, adds half the volume of alcohol, and titrates with aqueous $\frac{N}{2}$ soda solution.

With regard to the expression of the results, the author proposes that for the acid number, as well as for the saponification number, Koettstorfer's method of calculation should be adhered to. H. H. B. S.

On Solid and Liquid Siccatives. H. Amsel. (*Zeit. angew. Chem.*, 1897, 303-306 and 344-347.)—In this paper the author gives a description of his further work on this subject, and replies to some of Weger's minor criticisms (ANALYST, xxi., 261 and 300). The method of analysis now recommended is a combination of his own with that proposed by Weger, and comprises the determination of mineral matter (free and combined), moisture, solubility in chloroform and alcohol, acid value, saponification value, and ammonia reaction.

The total mineral matter is estimated in the ash, and the insoluble mineral matter in the portion insoluble in chloroform, as described by Weger. The acid value is determined in alcoholic mixture and also in chloroform, the latter giving a higher result, and not the true acid value.

The ammonia reaction consists in shaking the resinate with 10 per cent. ammonia, filtering and adding acid or water, when, if resin be present in excess, there should be a precipitate. But even with 2·5 per cent. ammonia, the author obtained precipitates with samples in which he considered the resin present entirely in the combined state. As pure colophony is soluble in the cold in 1 per cent. ammonia, experiments were made with that strength; but though the results were more satisfactory, they were by no means certain.

The moisture is determined by drying at 90°-95° C. In the author's samples it varied from 0 to 33 per cent., the usual amount being from 2 to 6 per cent.

A direct determination of the resin acids by Laudin's modification of Twitchell's process (*Chem. Zeitung*, 1897, iv., 25) has not, so far, given satisfactory results.

In analysing liquid siccatives, the solvent (turpentine-oil) is determined by drying a weighed quantity at 150° C., the mineral matter in the ash, and the acid value in alcoholic mixture. The acid value will often distinguish between metallic linoleates and resinates. Thus a liquid siccative prepared from manganese linoleate gave 45, whilst one from manganese resinate showed 100. They also behave differently with regard to the end-point of the titration, the red colour rapidly disappearing in the case of metallic resinates. A practical test should also be made by mixing a pure linseed-oil with 5 to 10 per cent. of the siccative, and noting the time required for drying. C. A. M.

On the Behaviour of Shellac Resin Acids in Gladding's and Twitchell's Methods. F. Ulzer and R. Defris. (*Zeit. anal. Chem.*, 1897, xxxvi., 24-27.)—In the separation of fatty and resin acids by Gladding or Twitchell's method the authors found that the resinous acids of shellac behaved quite differently to the ordinary resin acids. For example, a sample of dark shellac which contained 0·05 per cent. of unsaponifiable matter yielded by Gladding's process only 13·76 per cent. of "resin acids," so that in this respect they appeared to be more nearly related to the fatty acids than to the genuine resin acids. The silver salts of the shellac acids differed from the colophony acids by being practically insoluble in ether.

The acids of the brown shellac gave by Twitchell's method 66·56 per cent. of "resin acids" not esterified by the passage of the hydrochloric acid gas through the alcoholic solution. By shaking out the petroleum spirit solution of the acids and esters

with dilute sodium hydrate, an ester was obtained which formed a light-yellow semi-transparent resin-like mass which had a saponification number of 199·5.

The acids of an orange shellac, having acid number 53·05 and saponification number 200·98, gave by Twitchell's process 72·89 per cent. of resin acids which could not be esterified. Therefore the shellac acids appear to behave to some extent like fatty acids, since part of them form esters on being treated with hydrochloric acid gas in acid solution.

Specimens of Angola-Copal and Kauri-Copal when examined by Twitchell's process showed respectively 86·01 and 86·37 per cent. of resin acids.

See also ANALYST, xvi., 169, and xx., 60. C. A. M.

Estimation of Guaiacol by Demethylation. M. Adrian. (*Arch. de Pharm.*, 1897, ccxxxiv., 286.)—The process here described is a modification of that of Béhal and Choay (*Jour. Pharm. Chim.* [5], xxvii., 254). One hundred grammes of the sample to be examined are placed together with 10 c.c. of water in a 250 c.c. flask. This is connected with a flask in which hydrobromic acid is liberated and which has an outlet tube connected with a reflux condenser. A bulb-tube is placed between the flask containing the guaiacol and the generating flask, in order to prevent any liquid being sucked back into the latter during cooling, and the gas, after leaving the reflux condenser, passes through two wash-bottles containing water. The hydrobromic acid is generated by the action of water on phosphorus tribromide, and is passed slowly through the guaiacol, which is gently warmed after thirty minutes. The demethylation is complete in less than an hour with poor samples of guaiacol, but usually an hour and a half is required.

When cool, the contents of the flask are diluted with 500 to 600 volumes of water, and distilled by means of a current of steam to remove volatile substances (monophenols). The pyrocatechin and homopyrocatechin in the residue are extracted with ether, the solvent slowly evaporated, and the residue dried. The two substances are separated by means of benzene, in which the former is completely soluble, and can be crystallized out and weighed. From the amount of pyrocatechin the quantity of guaiacol in the sample can be calculated within 5 or 6 per cent. It is essential that the benzene should contain not the slightest trace of moisture or the crystallization of the pyrocatechin will be incomplete; and even with perfectly dry benzene the mother liquor must be concentrated and a second crystallization made. C. A. M.

The Detection of α-Naphthol in the Presence of β-Naphthol. E. Leger. (*Jour. Pharm. Chim.*, 1897, v., 527-529.)—The reagent is a freshly-prepared solution of sodium hypobromite, made by mixing 30 c.c. of soda solution (36° Bé) with 100 c.c. of water, and then adding 5 c.c. of bromine, and shaking.

α-Naphthol in a saturated aqueous solution gives with the above reagent a dirty-violet coloration, or even precipitate, which is still pronounced when the saturated solution is diluted with nine volumes of water.

β-Naphthol in saturated solution gives a yellow colour, passing to green and

then back again to yellow. If the saturated solution be diluted with its own volume of water, and two drops of the hypobromite solution added, a yellow colour is produced, but this, on shaking the liquid, immediately disappears.

In testing a mixture, a saturated solution is to be prepared, diluted with its own volume of water and 2 drops of the reagent added. The presence of 1 part of α-naphthol in 100 parts of β-naphthol is thus easily recognised. C. A. M.

The Methods of Testing Rose-Oil. R. Jedermann. (*Zeit. anal. Chem.*, 1897, xxxvi., 96-102.)—From an extended experience of the properties of genuine rose-oil, the author considers that the solidifying temperature and the sulphuric acid test are not of much value. The latter consists in mixing 5 drops of the oil with 25 drops of concentrated sulphuric acid, and then adding 10 c.c. of alcohol (specific gravity 0·8). With geranium-oil the solution at once becomes turbid, whilst with genuine rose-oil it is said to remain practically clear and colorless. Few genuine specimens of East Roumelian oil, however, remain clear, as traces of resinous matter distilling over with the oil often cause turbidity.

The solidifying point, which in genuine oils may deviate in either direction from the limits 17·5° to 20° C., is equally inconclusive, and the author places more reliance on the refractive index. The average for rose-oil at 30° C. is 43° 30′, that of geranium-oil being 41° 30′. The specific gravity may also give some indication as to the purity of an oil. At 30° C. this constant in genuine rose-oil varies between 0·8555 and 0·8645, and in geranium-oil between 0·883 and 0·8895. But in the author's opinion the most reliable tests are the expert judgment of the odour and the practical results obtained in the use of the oil (*cf.* ANALYST, xx., 48). C. A. M.

Estimation of Carbon Disulphide in Alcohol, Carbon Tetrachloride, etc., and a Method for the Purification of the latter. W. Schmitz-Dumont. (*Chem. Zeit.*, 1897, xxi., 487 and 510.)—Although the processes for the estimation of carbon disulphide in alcohol based on its conversion into potassium xanthate can be carried out smoothly, especially if the product is oxidized with solid permanganate and the sulphuric acid determined by means of barium chloride, yet they are not trustworthy because the initial reaction between the disulphide and the excess of caustic potash is not quantitative. If 10 c.c. of impure alcohol, containing about 0·1 gramme of CS_2, are warmed to 50° or 60° C. for twenty minutes with 20 c.c. of alcoholic lead acetate and 10 c.c. of normal alcoholic potash, the whole of the sulphur is recovered as lead sulphide, which may be oxidized to sulphate by bromine and nitric acid, dissolved in sodium acetate, and precipitated as barium sulphate. The results are quite satisfactory, and the scheme would probably work equally well with carbon tetrachloride; but the author finds on the whole that the method described below is quicker and better.

Processes depending on the use of phenylhydrazine are objectionable (1) in the case of benzene, etc., because of the relatively large solubility of the precipitate in the alcohol employed, which causes the figures obtained to be too low; and (2) in the case of carbon tetrachloride they are useless owing to the simultaneous formation

of a crystalline normal or basic hydrochloride of the reagent—both of which bodies are described fully in the original paper.

The following process is available for the estimation of CS_2 in all liquids or gases which can be brought into contact with alcoholic silver solution and aniline, and which do not contain ingredients liable to prevent the formation of AgS. To every 10 c.c. of the suspected fluid are added 50 c.c. of a 5 per cent. alcoholic solution of silver nitrate and 5 c.c. of aniline, and the mixture is heated for half an hour at 50° or 60° C. When the amount of CS_2 present is absolutely unknown, a considerable excess of aniline may be introduced (1 gramme $CS_2 = 2{\cdot}44$ grammes, or 2·51 c.c.; 1 c.c. $CS_2 = 6{\cdot}41$ grammes, or 6·6 c.c. of $C_6H_5NH_2$), and the silver added in instalments so long as a precipitate forms, the liquid being warmed each time until it becomes clear. There is little fear of loss by proceeding in this manner, but, if desired, the operation can be repeated when the necessary proportions have been arrived at. The silver sulphide, contaminated with metal reduced by the aniline, is thrown on a very small asbestos filter, washed with alcohol and ether by the aid of the pump, and melted with sodium carbonate and nitre. The melt is dissolved in water, acidified with nitric acid, diluted considerably, and the S determined with barium. The yield approaches closely to the theoretical, but great care must be taken regarding the purity of the different reagents. Gases should be passed through the mixed silver solution and aniline maintained at a temperature of about 60°, the absorption being complete.

In order to remove CS_2 from commercial CCl_4, $1\frac{1}{2}$ times as much caustic potash as is needed to combine with the disulphide is dissolved in an equal weight of water, and, together with 100 c.c. of alcohol, introduced into 1 litre of the chloride. After heating to 60° for thirty minutes, the xanthate is extracted by the addition of water, the aqueous liquid run off, and the entire process repeated twice again with half the original amount of alkali. Finally, 500 c.c. of water are shaken with the chloride until the separation is rapid and complete, the product dried with solid caustic potash, or preferably, metallic sodium, and distilled over paraffin to eliminate the C_2Cl_6. So prepared, it gives no sulphur precipitate with silver and aniline, and it boils constantly at 76·3° C. at 760 mm., the thermometer being in the vapour.

F. H. L.

Estimation of Nitrogen in Guanos. V. Schenke. (*Chem. Zeit.*, 1897, xxi., 490.)—The experiments on which the author's last communication on this subject (ANALYST, xxii., 77) was based having been conducted on old samples of guano, he has repeated them on fresh specimens coming from Peru and Damaraland. His conclusions are the same as before, especially as concerns the Haselhoff extraction process, which, although it can be modified so as to give useful results, thus becomes too tedious for practical work.

Schenke now calculates the nitrate nitrogen by deducting the quantity yielded by the Kjeldahl process from the total; for some of the nitrogen in uric acid is converted into ammonia on distillation even with magnesia, and therefore the difference between this amount of soluble nitrogen and that obtained by employing caustic soda.

or potash, as in Ulsh's reduction method, cannot truly represent the nitrogen present as nitric acid. F. H. L.

A Substitute for Hide Powder for Use in the Determination of Tanning Material. W. Schmitz-Dumont. (*Zeit. für öffent. Chemie*, iii., 209.)—The author refers to the difficulty of preparing hide powder of good uniform quality, which is so essential to its successful use in estimating the value of tanning agents, and describes experiments made with the object of finding a substance more suited to the purpose.

Experiments made with gelatin hardened with alum and chromic acid not proving successful, the author tried formalin-gelatin, prepared as follows: Thick filter-paper was saturated with a 10 per cent. gelatin solution, and laid upon glass rods to dry. When dry, it was immersed for twenty-four hours in a 2 per cent. formalin solution, and afterwards dried at 95° C. It was then cut up into strips, which were further reduced to powder by being passed through a mill. It was then again immersed for twenty-four hours in a 2 per cent. formalin solution, the fluid pressed out, and the powder dried at 100° C. until 50 grammes, dried separately, lost only about 0·05 gramme. The preparation was now freed from trioxymethylin by digestion in hot water in a Koch's extraction apparatus, until 100 c.c. of the effluent gave no formaldehyde reaction with alkaline resorcin solution. The water was then pressed out and the powder dried in a water-bath. The finished preparation, which yielded quite an unimportant quantity of soluble matter on digestion in water, was compared with a good hide powder by means of parallel experiments, and, so far as these were taken, with very favourable results. H. H. B. S.

Analysis and Detection of Artificial Silk. P. Truchot. (*Ann. de Chimie Analyt.*, ii., p. 121.)—Artificial silk, like natural silk, when treated with Schweitzer's reagent, swells up and dissolves, but is distinguished from the latter by a precipitate of cellulose forming on dilution, or on the addition of hydrochloric acid.

The deep yellow, syrupy solution obtained by the action of 60° B. (S.G. 1·712) sulphuric acid turns dark-blue in presence of diphenylamine sulphate. This reaction, as well as the rose coloration produced by brucine sulphate, indicates the presence of nitric acid due to the incomplete reduction of trinitrocellulose. It is an extremely delicate test, and can also be performed directly on the fabric; all the artificial silk threads of which, when dipped in diphenylamine sulphate solution, turn to a deep blue, leaving those of the natural silk unaffected.

The specific gravity of artificial silk is 1·490, that of the natural undyed fibre being 1·367 to 1·357. The sample examined by the author contained 1·52 per cent. of ash and 0·23 per cent. of nitric acid, corresponding to 1·63 of tri-nitrocellulose. C. S.

Estimation of Ash in Crude Sugars. Schrefeld. (*Zeits. Rubenz.*, xlvii., 560; through *Chem. Zeit. Rep.*, 1897, 149.)—The author finds that the ash of sugar loses weight in a muffle at a temperature of 700° C., and that at 850° or 900° it melts and begins to volatilise. Some of the constituents of the ash are, therefore, more volatile than the potassium sulphate which it contains. F. H. L.

INORGANIC ANALYSIS.

A Reaction of Carbon Monoxide. A. Mermet. (*Rev. de Chimie Analyt.*, v., pp. 130-133.)—The author finds that a weak solution of potassium permanganate, acidified with nitric acid, is decolorized by carbon monoxide, the reaction being more rapid in presence of silver nitrate. The time varies between one and twenty-four hours for air containing 0·2 to 0·02 per cent. of carbon monoxide.

The silver nitrate solution should contain 2 to 3 grammes of the crystallized salt per litre. The permanganate solution is prepared by boiling 1 litre of distilled water with a few drops of pure nitric acid, and destroying any organic matter present by adding a few drops of permanganate solution. When cold, 1 gramme of permanganate crystals and 50 c.c. of pure nitric acid are added, and the solution stored away from light and dust.

The reagent is prepared, immediately before use, by mixing 20 c.c. of the silver nitrate solution with 1 c.c. of the permanganate solution, 1 c.c. of pure nitric acid, and 28 c.c. of distilled water freed from organic matter. To apply the test, the reagent is poured into a flask containing the air under examination; or—since dust or reducing gases may also decolorize the reagent—the air is purified by filtration and passage through absorptive reagents, so that, the presence of a reducing agent being detected by the first method, its nature may be ascertained by the second. The presence of sulphur is detected by the brown tinge due to silver sulphide imparted to the reagent.

In testing suspected air—*e.g.*, from a mine—the sample is collected in the usual manner, the inlet of the bottle being provided with a cotton filter in the case of a dusty atmosphere. A check experiment is performed with normal air. C. S.

Estimation of Oxygen in Illuminating Gas. O. Pfeiffer. (*J. Gasbeleucht*, 1897, xl., 354; through *Chem. Zeit. Rep.*, 1897, 148.)—The amount of oxygen in 100 c.c. of coal-gas can be determined colorimetrically in a Bunte burette over 5 c.c. of caustic potash by adding 0·2 gramme of pyrogallol dissolved in 2 or 3 c.c. of oxygen-free water. The absorption is complete in five minutes, and the colour first darkens and then becomes paler again. It is not altered by ordinary variations in temperature, but changes in the proportions of the reagents affect it. Sulphuretted hydrogen gives it a wine-red shade. If 1 per cent. of oxygen exists in the gas, the colour is produced instantly; but if only 0·25 per cent. is present, the burette requires shaking for five minutes.

To prepare a series of standard tints, 30 grammes of sugar and 30 c.c. of 1 : 3 sulphuric acid are boiled in 1 litre of water for fifteen minutes, and 85 c.c. of 1·3 caustic soda added. This liquid is mixed, drop by drop, with water in test-tubes until the colours match those yielded by artificially-produced mixtures of coal-gas and oxygen treated as above. The standards are permanent if preserved in the dark.

F. H. L.

Simple and Rapid Analysis of Nickel Castings; Separation of Nickel and Cobalt by the von Knorre Method. J. Albahary. (*Rev. de Chimie Analyt.*,

v., 102-104.)—Five grammes of the substance are dissolved in 50 c.c. of nitric acid, evaporated to dryness, taken up by 10 c.c. of dilute sulphuric acid, and boiled for forty-five minutes.

Silica is determined by filtering, igniting, and weighing; *copper* by precipitation on the water-bath by means of 50 c.c. of saturated hydrogen sulphide.

Iron.—After heating to drive off the hydrogen sulphide, the solution is made up to 250 c.c., the iron being thrown down from 100 c.c. by ammonia, and freed from nickel by reprecipitation.

Nickel and Cobalt.—The other 150 c.c. of solution are, after the addition of 5 grammes of sodium sulphate, electrolyzed for five hours by a current of half an ampère, to throw down nickel and cobalt.

Magnesium is estimated in the residual liquid, as ammonio-phosphate.

Separation of Nickel and Cobalt.—The metals deposited on the negative pole are dissolved in dilute sulphuric acid, and the warm solution treated with an excess of a hot saturated solution of nitro β-naphthol in 50 per cent. acetic acid in presence of a little hydrochloric acid to prevent the simultaneous precipitation of nickel. After leaving the precipitate to subside for three hours, and making certain that all the cobalt is thrown down, it is first washed with cold, then with hot, 12 per cent. hydrochloric acid, and finally with boiling water; then dried and ignited with 2 grammes of crystallized oxalic acid in a current of hydrogen, the metallic cobalt being weighed in the crucible. Nickel is estimated by difference or by precipitation with potash, after removing by evaporation most of the acetic acid from the solution.

Sulphur is estimated by the Carius or Campredon method; *carbon* by the Corleiss (chromic acid and copper sulphate) or Viborg method. C. S.

Determination of Phosphoric Acid as Phospho-Molybdic Anhydride. Woy. (*Chem. Zeit.*, xxi., 441.)—By following up the work of Meineke and Hundeshagen, the author has succeeded in perfecting a method by which phosphoric acid in plant-ashes, fertilizers, and raw phosphates can be determined by means of molybdenum, without the usual subsequent precipitation with magnesia-mixture. The method is as follows:

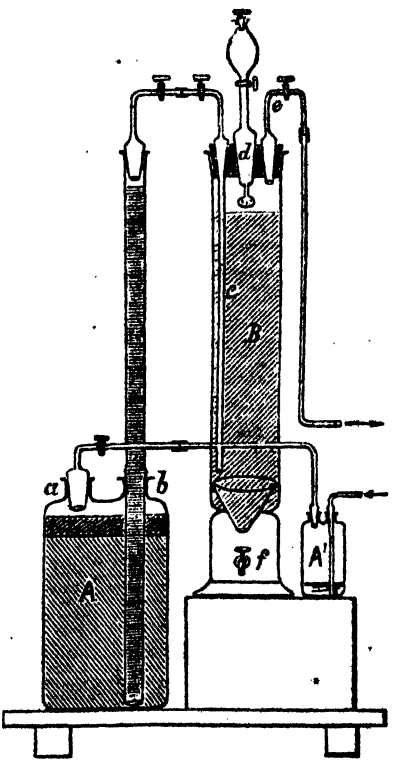
Reagents.—1. A 3 per cent. solution of ammonium molybdate, made by dissolving 120 grammes in 4 litres of water.

2. Ammonium nitrate solution; 340 grammes in 1 litre.

3. Nitric acid of 1·153 specific gravity, containing 25 per cent. HNO_3.

4. Solution for washing; 200 grammes ammonium nitrate and 160 c.c. nitric acid in 4 litres.

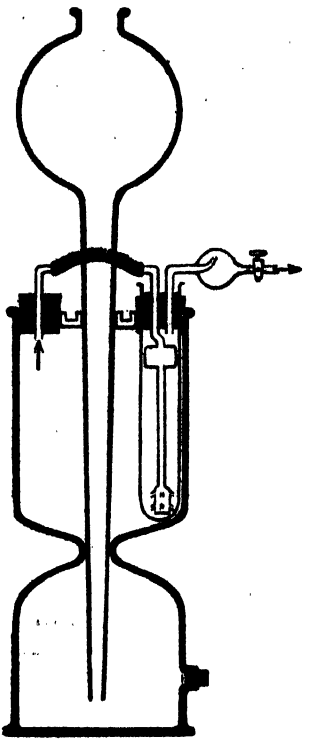
Procedure. — 0·1 gramme P_2O_5 requires for the formation of the anhydride $24MoO_3$, P_2O_5, 2·9856 grammes ammonium molybdate, which is equivalent to 100 c.c. of the 3 per cent. solution. Therefore, in working with 0·5 gramme of substance, 5 c.c. of the solution are required for every 1 per cent. P_2O_5; but an excess of 20 c.c. above the theoretical quantity should be allowed. Usually 10 c.c. of nitric acid suffice, but the quantity can be increased to 20 c.c. in certain cases.



Thirty c.c. ammonium nitrate solution and 10 c.c. or 20 c.c., as the case may require, of nitric acid, are measured together and added to the solution containing

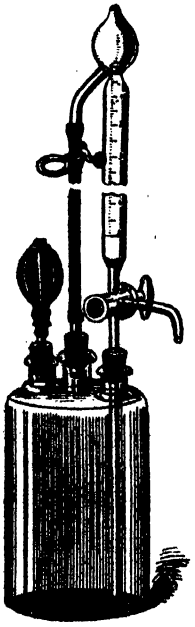
the phosphoric acid. The whole is then heated over a lamp until bubbles commence to rise. The necessary quantity of molybdate solution, also heated to the same extent, is then allowed to flow into the middle of the hot solution, which is meanwhile kept in motion by giving the beaker a circular movement with the hand. The precipitate forms almost immediately, and in ten or fifteen minutes subsides sufficiently to filter off. The author filters through a porcelain Gooch crucible with the assistance of atmospheric suction. The precipitate is washed by decantation with 50 c.c. of hot washing solution, and then redissolved into the same beaker with 10 c.c. of an 8 per cent. ammonia solution. Twenty c.c. ammonium nitrate, 30 c.c. water, and 1 c.c. molybdate solution are then added. The whole is now heated over a lamp as before, and re-precipitated by adding 20 c.c. of hot nitric acid drop by drop, the fluid meanwhile being kept in motion as before. The precipitate soon subsides, and is then filtered off through the same crucible and washed with the washing solution. The incineration is accomplished by placing the porcelain Gooch crucible inside a nickel crucible, and heating gradually until the bottom is of a dull red heat. In about fifteen minutes, at this temperature, the yellow precipitate is completely converted into the black anhydride $24MoO_3$, P_2O_5, containing 3·946 per cent. P_2O_5.

H. H. B. S.



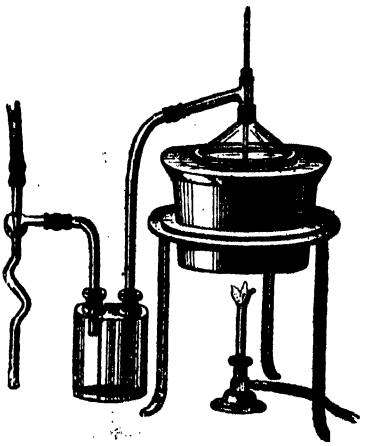
APPARATUS.

A New Apparatus for Purifying Gases. **A. J. J. Vandevelde.** (*Chem. Zeit.*, xxi., 445.)—The apparatus shown in the accompanying illustration allows of gases being easily and freely passed through it, and yet acts as a thoroughly efficient absorber. It also admits of the sulphuric acid used for drying being conveniently renewed. It consists of a large Woulff's bottle A, in which the carbonic acid is absorbed, and a cylindrical vessel B, in which the gases are dried. The Woulff's bottle is three parts filled with solid caustic potash, upon which is a layer of quicklime. The tube *b* contains soda-lime and the small Woulff's bottle A' sulphuric acid. The funnel tube *d* is provided with a stopcock, and at its lower end is a hollow perforated globe. The cylinder B is filled with broken glass moistened with sulphuric acid. The direction in which the gases are passed through the apparatus is shown by the arrows. When the sulphuric acid requires to be renewed, it is drawn off by means of the tap *f*, and a fresh supply introduced through the funnel tube *d*.



H. H. B. S.

New Gas Apparatus. H. Witzel. (*Chem. Zeit.*, 1897, xxi., 536.)—This apparatus combines the functions of the Kipp generator and the ordinary washing or drying-tubes, so that it becomes more convenient to handle. It will also be observed that the purifying vessel is specially designed to prevent any splashing of the liquid employed. F. H. L.



WITZEL'S GAS APPARATUS.

New Laboratory Apparatus. (*Chem. Zeit.*, 1897, xxi., 351.)—*Peters and Rost's Automatic Burette.*—This apparatus can either be made to carry a burette or a pipette, but the latter arrangement is more generally useful. To fill the measuring vessel, the pinch-cock is closed, the tap set so that the burette and vessel are in connection, and the liquid pumped up by squeezing the rubber ball; the tap is then closed and the pinch-cock opened, when any excess of the solution that has accumulated in the top bulb runs back into the bottle, and the 0-point is automatically set. The liquid can then be run off by turning the 3-way tap in the proper direction. F. H. L

NEW LABORATORY APPARATUS.

Haussmann's Vacuum Apparatus. (*Chem. Zeit.*, 1897, xxi., 351.)—This consists of a cylindrical porcelain still provided with a ground lip on which an inverted glass funnel rests, making a joint in the manner illustrated. The apparatus is therefore cheap, simple, and can be used on any water-bath. F. H. L.

HAUSSMANN'S VACUUM APPARATUS.

THE ANALYST.

OCTOBER, 1897.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

NOTE ON COMMERCIAL GROUND CASSIA.

By W. F. Keating Stock, F.I.C.

(*Read at the Meeting, June* 2, 1897.)

I have analysed a large number of samples of commercial ground cassia during the last three years, and among them I have not found one which corresponded in composition with samples of genuine cassia lignea ground in the laboratory. In the majority of cases the difference was due to the presence of sand and earthy matters generally, these predominating over the natural ash to the extent of from 1 per cent. up to 9 per cent. In two cases exhausted ginger was present, and in several others the sample was entirely composed of *Cassia vera*, which differs considerably in quality and composition from the ordinary *Cassia lignea*.

With regard to the presence of extraneous earthy matter in ground cassia, one is inevitably driven to the conclusion that it does not come there by honest means. For if the nature of the process by which cassia is collected and prepared for market in its unground condition is considered, it is seen to be a cleansing process, and that the presence of sand and dirt is avoidable. This view is supported, I think, by the following analyses made in my laboratory:

Average total ash in genuine *Cassia lignea*	... ...	= 1·92 per cent.
,, ,, in high-class commercial samples	...	= 2·68 ,,
,, ,, in ordinary commercial samples	...	= 5·09 ,,
Variations of total ash found in ordinary samples		= 3·18 – 11·60 ,,

One would not like to say that small variations in the proportion of natural ash are impossible, but the variations cannot by any reasonable argument be made to embrace sand or earthy matter, and when these occur to the extent of more than a few tenths per cent., the sample should be looked upon with suspicion.

The detection of exhausted ground ginger in admixture with ground *Cassia lignea* offers no difficulty to the analyst, since the starch granules contained in each are so entirely dissimilar. But a rapid and accurate method of determining the relative proportions of the two is not, perhaps, so easy to arrive at. The ether extract, alcohol extract, water extract, total ash, soluble ash, and phosphoric acid, all failed

to give me any useful factor. I, however, found a valuable aid to the determination in the proportion of woody fibre in the water-free substance.

The following table will show how the woody fibre supplies the necessary data for calculation:

Samples Analysed.	Moisture.	Woody Fibre in Undried Sample.	Woody Fibre in Water-free Sample.
Commercial ground cassia (five samples) ...	12·17	24·46	27·70
Laboratory ground cassia	16·85	22·56	27·10
Suspected sample	13·23	15·33	17·60
Exhausted ginger	11·84	5·03	5·70

If C represents the cassia in a dried sample, D the woody fibre in the sample, and E the fibre in dried exhausted ginger, then C is obtained as follows:

$$C = \frac{(D - E)100}{27{\cdot}5 - E}.$$

The proportion of cassia so obtained is *dry* cassia, and must be corrected for the moisture present in the sample.

Owing to the importance of the fibre in the foregoing formula, it must, of course, be determined with great care, and, without going into much detail, I may mention that in my practice 3 grammes of finely-ground cassia are boiled in a 600 c.c. flask attached to a reflux condenser, with 200 c.c. of dilute sulphuric acid, containing 1·25 per cent. of ordinary strong acid, for thirty minutes. The liquid is then filtered through a linen-cloth filter, using a filter-pump; the residue is washed free from acid with boiling water, returned to the flask, boiled again for thirty minutes with 200 c.c. of a 1·25 per cent. solution of sodium hydrate. The flask is then filled up with cold water, and allowed to stand for twenty minutes, when the liquid is again filtered through the same cloth filter, and the fibre is thoroughly washed with boiling water. Finally it is treated with 50 c.c. of dilute hydrochloric acid, containing 12·5 c.c. of the ordinary pure acid. It is washed free from every trace of acid with boiling distilled water, transferred to weighed watch-glasses, dried to constant weight, ignited, and any mineral matter deducted.

The substitution of *Cassia vera* for *Cassia lignea* is a matter which cannot in the existing state of things be dealt with under the Sale of Food and Drugs Acts. It is generally admitted—and, indeed, it is quite obvious—that both in flavour and convenience in use *Cassia vera* is inferior to *Cassia lignea;* but since it is "cassia," no penalty attaches to its substitution for *Cassia lignea* unless *Cassia lignea* has been specifically demanded.

I have drawn attention to this variety of cassia in the interests of Public Analysts who may not yet have met with it, and to whom it might prove misleading. It differs from *Cassia lignea* in two important points. In the first place, it contains much larger starch granules, and, in the second place, it yields with cold water a tenacious glairy mass, owing to its content of mucilage. The starch granules of *Cassia vera* do not differ greatly in their larger forms from those of exhausted ginger,

and it behoves the Analyst meeting with *Cassia vera* in admixture with *Cassia lignea* not to depend too much upon the microscope, but to look closely into the general characters of the sample.

Some analyses of commercial samples of *Cassia vera* have been made in my laboratory, and the figures so obtained are contrasted with similar figures for *Cassia lignea* in the following table:

Constituent Sought.	*Cassia lignea* (several samples).	*Cassia vera* (several samples).
Moisture	12·17	11·15
Total ash	5·36	5·15
Soluble ash	1·20	1·45
Phosphoric acid	·19	·13
Woody fibre in water-free sample	27·70	19·50

NOTE ON THE BACTERIOLYSIS OF GELATIN.

By Dr. S. Rideal, D.Sc., and R. Orchard.

(*Read at the Meeting, June* 2, 1897.)

In ordinary bacteriological work for water analysis and other purposes, free use is made of gelatin media, and one of the distinctions between bacteria is founded on their liquefying, or not liquefying, gelatin. The jelly runs down the test-tube or collects on the surface of the plate, and forms a pool, which is fluorescent, or colored, or possessed of odours, according to the nature of the pure culture present.

Although an amount of work has been published on the changes resulting from the decomposition of various organic matters, especially albumin, no record of any experiments, or series of experiments, could be found which demonstrated quantitatively the chemical changes that take place when the ordinary gelatin medium used in bacteriological investigations is liquefied; in fact, the published analyses of commercial gelatin itself were very imperfect.

With the object, therefore, of determining the changes produced when gelatin is in process of liquefaction by bacteria, we have made a series of experiments on the following lines:

A quantity of gelatin medium was prepared, containing 10 per cent. of "Coignet's best gelatin" and 10 per cent. of Pasteur's solution, made up with Rochelle salts in the place of ammonium tartrate, in order to avoid the introduction of ready-formed ammonia; this was made faintly alkaline with sodium carbonate, and clarified in the usual manner. After heating the solution to 30° C., so as to be quite fluid, quantities of 20 c.c. were pipetted into 6 oz. conical flasks, plugged with cotton-wool, and subsequently sterilized by heating to 100° C. on three successive days. These were then inoculated from an active culture of the organism, and incubated at "room temperature" for the given time. Conical flasks were employed, in order that the liquefaction of the gelatin should proceed at the maximum rate,

and consequently the organisms were cultivated as far as possible under aerobic conditions. Petri's dishes were tried, but, owing to the difficulty of manipulation without loss when the medium was fluid, they were abandoned. The different flasks showed progressive liquefaction of the gelatin according to time. The liquid produced was in all cases alkaline, had a slight putrefactive odour, was turbid, and contained no sulphuretted hydrogen.

In the subsequent analyses, after the different periods, the contents of the flasks were warmed to the same temperature—30° C.—rendered faintly acid with acetic acid, and heated to 100° C., in order to ascertain whether the bacteria in their growth had produced any weighable quantity of cellulose or coagulable albumin. No precipitate was obtained which could be estimated, except in one case—the sixteen days' culture of *B. fluorescens liquefaciens*, when the precipitate by heat amounted to 0·06 per cent. (= 0·01 N). The contents of the flasks were cooled again to 30° C., diluted with sterile water to 250 c.c., and aliquot portions carefully measured out at this temperature for each determination. In this way strictly comparative results were obtained, independent of the slight evaporation from the gelatin medium. The results were controlled in each case by a determination of the total nitrogen.

The gelatin and albumoses were estimated by Kühne and Chittenden's method of precipitation with saturated ammonium sulphate solution, dissolving the precipitate in warm water, dividing, and determining the total nitrogen in one portion, and in the other, very exactly, the SO_3, then subtracting the nitrogen due to ammonium sulphate, a process which we prefer to that of direct weighing of the precipitate.

The albumoses were determined separately by precipitating a portion of the original solution with Stutzer's reagent (an emulsion of copper hydroxide in glycerin and water), washing, and estimating the nitrogen in the precipitate.

The volatile bases were estimated in a portion of the original, by distillation with caustic soda and titration of the distillate. A further portion of the original was precipitated with alcohol, filtered, and the nitrogen content of the filtrate returned as bases and extractives.

The two liquefying organisms selected were: (i.) *B. prodigiosus*, from an active gelatin culture, and (ii.) *B. fluorescens liquefaciens*, freshly obtained from tap-water. P. F. Frankland describes a gelatin-tube culture of *B. prodigiosus* in the following words: "Grows very rapidly, liquefying the gelatin in the form of a conical sack, which soon extends across the top of the tube, and, gradually passing downwards, involves the whole tube. The liquid is very turbid, with an abundant flocculent deposit of intense crimson colour." And a stab culture of *B. fluorescens liquefaciens* (Flügge) as under: "In the path of the needle there is a whitish growth, whilst a funnel-shaped depression, containing liquid gelatin, forms on the surface; the liquefaction gradually stretches across the tube, and finally the whole contents are fluid and of a fluorescent green colour, whilst a white deposit collects." In the initial plate cultivations, after fourteen days at 20° to 21° C., the gelatin was found to be only partially liquefied by the *B. prodigiosus*, so that our attention was chiefly confined to *B. fluorescens liquefaciens*. A number of flasks were inoculated with this organism, the contents being analysed after *one day*, when only a superficial liquefaction of the gelatin had taken place; *two days*, when about half had been liquefied;

three and a half days, when the liquefaction of the gelatin was quite complete; and finally after *sixteen days*.

The following is a tabulated summary of the results obtained:

Calculated as Grammes of Nitrogen per 100 *c.c.*

Incubated at 20° to 21° C.	Total Nitrogen.	Gelatin and Albumoses.	Albumoses.	Ammonia and Volatile Bases.	Bases and Extractives.	Peptone N unaccounted for.	Gelatin.	Albumin and Cellulose.
Blank (i.)	1·242	1·109	0·514	0·003	0·061	0·069	0·595	
,, (ii.)	1·246	—	0·528	0·004	—	—	0·581	
B. prodigiosus, 14 days ...	1·232	1·024	0·409	0·049	—	—	0·615	
B. fluor. liquefaciens, 1 day	1·33	1·141	0·402	0·028	—	—	0·739	
,, ,, 2 days	1·256	0·682	0·297	0·045	0·105	0·424	0·385	
,, ,, 3½ ,,	1·267	0·242	0·135	0·063	0·486	0·476	0·107	
,, ,, 16 ,,	1·26	0·216	0·081	0·168	0·742	0·124	0·135	0·01

It will be noticed from the analysis of the blank that the original dry gelatin contains roughly 50 per cent. of matter precipitable by Stutzer's reagent, so-called albumoses. In the early stages these albumoses seem to be first attacked by the organism; but subsequently their decomposition proceeds at an equal rate with that of the true gelatin.

A notable feature in this research is the small production of ammonia and volatile bases, in view of the fact that substances such as trimethylamine, indol, and skatol have been generally stated in analyses by other observers to be constant accompaniments of the liquefaction of proteids. That this is not accounted for by the volatilization of such bodies during the incubations is proved by the comparative absence of odour and of strong alkaline reaction in the air of the flasks, and in such loss not being indicated by the total nitrogens. Previous investigations have, however, been conducted with "nutrient gelatin," containing other proteids. The quantity of ammonia produced is insignificant, amounting, even after sixteen days' incubation with *B. fluorescens liquefaciens*, to only 0·168 gramme of nitrogen per 100 c.c., corresponding to 0·204 gramme of ammonia.

The figures for the nitrogen unaccounted for, which would be almost entirely peptones, are very interesting. The original gelatin solution containing 0·069 gramme per 100 c.c., this gradually increases as the liquefaction proceeds, until, with *B. fluorescens liquefaciens*, it reaches the maximum figure of 0·476, when the medium is just entirely liquefied, and then diminishes, after sixteen days, to 0·124, showing that the bacillus, after bringing about the decomposition of nearly all the gelatin and albumoses, subsequently attacks the peptone, which has meanwhile been produced, with a corresponding increase of bases and extractives soluble in alcohol.

It is known that certain bacteria produce peptonizing enzymes, and in the case of the *B. fluorescens liquefaciens* the organism appears, as shown above, to subsequently feed on the peptone produced by its enzyme.

In order to ascertain whether the enzyme is capable of liquefying the gelatin

without the aid of bacteria, a large quantity of gelatin medium was inoculated with *B. fluorescens liquefaciens*, and incubated at 20° C. After about five days, when the culture was entirely fluid, some of it was filtered, by a vacuum, through a Pasteur candle into a filtering-flask containing 100 c.c. of 10 per cent. gelatin that was quite sterile. When about 10 to 15 c.c. of the culture had passed through, the filter was removed, the neck of the flask plugged with cotton-wool, and the gelatin warmed to 30° C, so as to be able to mix the filtrate uniformly with the gelatin solution; it was then allowed to set quite firmly, and incubated at 20° C. As after a few hours the gelatin was not quite solid, it was removed from the incubator and kept in a room at about 10° C. In twenty-four hours the contents of the flask were semi-liquid, and after thirty-six hours quite liquid. It was proved to be sterile by microscopical examination and by attempts at subculture. The liquid did not smell putrid, and was not fluorescent; except that it was liquid, it appeared the same as the original gelatin solution. The contents of the flask were then analysed with the following results, calculated into grammes of nitrogen per 100 c.c.:

Total Nitrogen.	Gelatin.	Albumoses.	Ammonia.	Bases and Extractives.	Peptone.	Vol. Org. Acids.
1·232	·359	0·21	Nil	0·469	0·174	Nil.

The liquid was tested for the presence of peptone by dialysing a portion, and adding caustic soda and copper sulphate to the dialysate, when a strong biuret reaction was obtained; with the original gelatin solution similarly treated there was no reaction. That an enzyme is produced by *B. fluorescens liquefaciens* was further confirmed by repeating the above experiment on 15 per cent. gelatin containing Pasteur's solution as before, but not alkalized, when it was found to be liquefied in twenty hours at 17° to 18° C.

AN IMPROVED METHOD OF DETERMINING PROTEID AND GELATINOID SUBSTANCES.

By A. H. Allen and A. B. Searle.

In a paper recently read before the Society of Public Analysts (Analyst, this volume, p. 228), by Dr. S. Rideal and Mr. C. G. Stewart, a process of determining gelatin was described which was based on the treatment of the solution by chlorine, and drying and weighing the resultant precipitate. In the subsequent discussion, one of us suggested that several advantages might be gained by the substitution of bromine for chlorine, the nitrogen in the precipitate being subsequently determined by Kjeldahl's process instead of the precipitate itself being weighed.

We have since made a number of experiments on these lines, and have devised a modified process which materially lessens the time required for the determination of the proteid or gelatinoid matter in a substance, without impairing the accuracy of the result. The following mode of procedure is that which we have found most satisfactory:

A quantity of the solution, containing about 1 gramme of the albuminoid matter, is brought to a volume of about 100 c.c., and treated in a conical beaker with suffi-

cient dilute hydrochloric acid to render the liquid distinctly acid to litmus. Bromine-water is then added in considerable excess, and the liquid stirred vigorously for some time. The yellowish precipitate which separates is flocculent when first formed, but becomes more viscous after stirring, and, in great part, adheres to the sides of the beaker, which, with its contents, is allowed to stand for about half an hour, or until all the precipitate has settled. The liquid is then decanted through an asbestos filter.* The precipitate adhering to the beaker is washed several times with cold distilled water, the washings being poured through the filter. Occasionally, when most of the free bromine has been washed out of the precipitate, the liquid does not filter clear. It is therefore advisable to keep the washings separate from the filtrate, and, if necessary, to wash with sodium sulphate solution or with bromine-water. We make no attempt to weigh the precipitate, preferring to determine the contained nitrogen by the Gunning-Kjeldahl process. For this purpose, the contents of the filter-tube (including the asbestos and glass-wool) are returned to the beaker in which precipitation took place, 20 c.c. of strong sulphuric acid added, the beaker covered with a watch-glass, and heated over a piece of wire-gauze. When frothing has ceased, about 10 grammes of powdered potassium sulphate should be added, and the liquid heated strongly until colourless. It is then allowed to cool, diluted with water, an excess of caustic soda added, the ammonia distilled off, and the distillate titrated with standard acid. The percentage of nitrogen found when multiplied by the factor 6·33 (or in the case of gelatin by 5·5) gives the amount of proteid matter precipitated by bromine.

Experiment showed that the precipitates produced by bromine in solutions of the proteids are insoluble in water and in dilute hydrochloric acid. The extractive matters of meat, on the other hand, are only precipitated in concentrated solutions, and the precipitates formed are, in great part, dissolved on dilution, especially in presence of a little hydrochloric acid.

We have also found that, whilst the precipitates produced by bromine in solutions of the proteids are soluble in dilute caustic soda, the resultant solutions are not completely reprecipitated on acidulation with hydrochloric acid.

In order to further test the process, we have experimented upon the following proteid and gelatinoid bodies:

Commercial Gelatin.—A 10 per cent. solution of commercial gelatin was prepared by dissolving 50 grammes of Nelson's gelatin in warm water and diluting the solution to 500 c.c. In 10 c.c. measure of this solution (containing 1 gramme of gelatin) the nitrogen was determined directly by Gunning's modification of Kjeldahl's process. Another portion of 10 c.c. was diluted, treated with excess of bromine in the manner described above, and the nitrogen in the precipitate determined as before. As these two experiments gave concordant results (14·1 and 14·0 per cent. of nitrogen), we conclude that the bromine precipitated all the gelatin present.

Gelatin-Peptone.—A volume of 300 c.c. of the above gelatin solution was rendered acid by the addition of 8 c.c. of strong hydrochloric acid, and the liquid kept at a

* This is made by placing a little glass-wool in a cylindrical funnel (a vertical glass tube drawn out at the lower end), and covering it with a pad of pulped asbestos. If the filter be properly constructed, no water-pump will be required, and a perfectly clear filtrate will be obtained.

temperature of 100° C., with occasional agitation, until it no longer gelatinized on thorough cooling. It was then made up to its original volume, and the nitrogen determined in the precipitate produced by bromine in 10 c.c. of the solution (= 1 gramme of original gelatin). The result of this experiment gave 13·9 per cent. of nitrogen, which showed that bromine precipitated practically all the gelatin which had been converted into gelatin-peptone, as well as any undecomposed gelatin which might be present. From more recent experiments we are inclined to believe that the conversion of the gelatin was far from complete.

Commercial Egg-Albumin.—A 2 per cent. solution was prepared by dissolving 10 grammes of commercial egg-albumin (in scales) in warm water and diluting the solution to 500 c.c. In 50 c.c. of the solution (= 1 gramme of the original albumin) the nitrogen was determined direct as in the gelatin, the amount found being 8·82 per cent. Another portion of 50 c.c. was treated with bromine, and the nitrogen in the precipitate determined as before, 8·72 per cent. being the result obtained. Hence egg-albumin is completely precipitated by bromine.

Acid Egg-Albumin.—To 100 c.c. of the solution of egg-albumin 2·5 c.c. of strong hydrochloric acid was added, and the liquid kept at 100° C. for several hours, and with frequent agitation. After cooling, the liquid was treated with bromine, and the nitrogen in the precipitate determined. The result showed that the whole of the nitrogen passed into the bromine precipitate. In another experiment a known volume of standard hydrochloric acid was added to another portion of the egg-albumin solution, and the liquid kept at 100° C. for some time, as before. After cooling, such a volume of standard soda was added as would exactly neutralize the hydrochloric acid employed. The nitrogen in the precipitate produced by bromine was determined, and showed in this case, as in that in which when no attempt was made to neutralize the free hydrochloric acid, that the whole of the acid albumin was precipitated by bromine.

Another sample of commercial scale-albumin was converted into acid-albumin (syntonin) by heating it in 1 per cent. solution with hydrochloric acid for six hours. The nitrogen was then determined directly in the resultant liquid and in the bromine precipitate produced in different ways, as shown below. The figures are calculated to 100 parts of the original albumin, which was found to contain 9·88 per cent. of nitrogen and to yield 8·32 per cent. of ash on ignition. Hence the sample was far from pure.

	Nitrogen.
A. By direct Gunning-Kjeldahl process on syntonin solution ...	9·86 per cent.
B. By precipitate from unneutralized syntonin solution	9·76 ,,
C. By precipitate from nearly neutralized syntonin solution ...	9·69 ,,
D. By precipitate from syntonin solution, rendered strongly alkaline and then re-acidified	9·60 ,,
E. Precipitate from syntonin solution, made strongly alkaline by soda, bromine added, and the liquid acidulated after half an hour	6·69 ,,
F. Precipitate from syntonin solution, made strongly alkaline by soda, bromine added, and the liquid acidulated after twenty-four hours	3·52 ,,

From experiments E and F it appears that, in presence of excess of alkali, bromine causes such a change in a solution of syntonin as to prevent full precipitation occurring on subsequent acidulation. The change, which is probably due to the formation of hypobromite and its action on the proteid, appears to be gradual, since the precipitation was far less perfect after twenty-four hours' action than after only half an hour.

Digested Egg-Albumin.—One hundred c.c. of the original egg-albumin solution was acidulated with hydrochloric acid, and digested with pepsin for four hours. The liquid was then cooled, and divided into two equal parts. In one of these the nitrogen was determined directly, and in the other in the precipitate produced by bromine. The results showed that the precipitate formed by bromine in the solution of the mixed products of the digestion of egg-albumin by pepsin contains the total nitrogen of the original albumin.

Albumin-Peptone.—This was prepared by digesting the finely-divided whites of hard-boiled eggs for four hours with pepsin, in presence of free hydrochloric acid. The digested liquid was then raised to a temperature of 97° C. (by blowing in steam) to arrest any further action of the pepsin. The liquid was filtered and neutralized with sodium carbonate solution, and the precipitated syntonin filtered off. The filtrate was evaporated to a low bulk on the water-bath, and was then saturated with zinc sulphate. The precipitated albumoses were washed with a saturated solution of zinc sulphate, and the filtrate and washings diluted to 100 c.c. The total nitrogen was determined directly in one portion of the solution of peptone thus obtained, and the amount of nitrogen in the precipitate produced by bromine in another portion. The results showed that the mixture of peptones resulting from acid-pepsin digestion of egg-albumin is completely precipitated by bromine.

White of Egg.—Another series of experiments on fresh white of egg gave the following results:

	Nitrogen.	= Proteids.
In original white of egg	1·89 per cent.	11 96 per cent.
In precipitate by bromine	1·88 ,,	11·90 ,,
In precipitate by bromine from syntonin solution	1·89 ,,	11·96 ,,

Meat-Extractives.—Solutions of creatinine, asparagine, and aspartic acid were found to yield no precipitate with bromine. To test the powers on the mixture of meat-bases and "extractive matters" actually present in meat-extracts, we allowed some finely-divided raw beef to stand in contact with ten times its weight of water, with occasional agitation, for about six hours. The liquid was strained, and steam blown through the liquid until it had attained a temperature of 97° C. The coagulated albumin was filtered off, and the filtrate was measured. The total nitrogen in it was determined, and also the nitrogen in the small precipitate produced by bromine. In order to determine the latter more exactly, one-fourth of the filtrate from the albumin was evaporated to one-tenth of its bulk and excess of bromine added. The greater part of the precipitate produced dissolved on adding an equal measure of water, and on the addition of a few drops of hydrochloric acid further solution occurred. The remaining precipitate was filtered off and the nitrogen in it determined, the amount found being very trifling.

The following is a tabular view of the chief of the foregoing results :

Substance.	Nitrogen per cent.		Nitrogen multiplied by factor.		Factor employed.
	Total in Original Substance.	Precipitated by Bromine.	Total in Original Substance.	Precipitated by Bromine.	
Commercial gelatin ...	14·10	14·00	77·5	77·0	5·5
Gelatin-peptone	14·10	13·90	77·5	76·5	5·5
Commercial scale albumin	8·80	8·72	55·8	55·2	6·33
Syntonin from scale albumin	9·86	9·76 9·69 9·60	62·41	61·78 61·34 60·77	6·33
Digested scale albumin ...	8·89	8·81	56·3	55·8	6·33
Fresh white of egg ...	1·89	1·88	11·96	11·90	6·33
Syntonin from white of egg	1·89	1·89	11·96	11·96	6·33
Peptone from white of egg	0·70	0·69	4·43	4·37	6·33
Beef-extractives	0·33	0·004	2·11	0·03	6·33

These results fill certain blanks left by the experiments of Rideal and Stewart, and, while generally confirming their conclusions, show that by the very simple mode of operating adopted by us a complete precipitation and determination of proteid and allied matters can be effected, with fairly sharp separation from co-occurring organic matters.

On applying the bromine method to commercial meat-extracts, the following results were obtained. The solutions of the bovril preparations were not previously filtered, and therefore the figures include the nitrogen of the meat-fibre present :

	Nitrogen in Precipitate by Bromine.	× 6·33 = Proteids.
Liebig Company's extract	1·41 per cent.	8·92 per cent.
Seasoned bovril	1·94 ,,	12·28 ,,
Bovril for invalids	2·64 ,,	16·71 ,,

König and Bömer have recently shown that the proteid nitrogen in meat-extracts has generally been much over-estimated. They found a total of 1·17 per cent. of proteid nitrogen in Liebig Company's extract, which is equivalent to 7·41 of total proteids (mostly albumose).

Similarly, a recent analysis of Liebig Company's extract, made by entirely different methods, gave us 9·37 per cent. of total proteids.

The fact that bromine completely precipitates all proteid and gelatinoid matters, affords a convenient means of solving certain problems which have hitherto presented considerable difficulty. Thus, by saturating the liquid with zinc sulphate, and treating the filtrate with bromine, the real peptone formed in digestion-experiments might probably be accurately determined.

We have already applied this process to the vexed question of the existence of real peptones in meat-extracts. Thus, 5 grammes of the Liebig Company's extract was dissolved in 100 c.c. of water, and the solution saturated with zinc sulphate. On adding bromine to the filtered liquid, a precipitate was produced which redissolved on

diluting with water and adding hydrochloric acid. When the filtrate from the zinc sulphate precipitate was diluted with water and acidulated previously to adding bromine, no precipitate was formed. This experiment appears to decide the question of the presence of considerable quantities of real peptones in Liebig's extract in the negative, and hence confirms the conclusion of König and Bömer on this point.

We further propose to examine the applicability of the bromine process of precipitation to the examination of albuminous urine, and to other cases in which a rapid determination of proteid and gelatinoid matters is a desideratum.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Distillation of Highly-diluted Ethyl Alcohol (1 in 3,000 to 1 in 10,000). Nicloux and Bauduer. (*Ann. de Chim. Analyt.*, vol. ii. [11], pp. 202-204.)—It has been found by experience that by collecting at the first distillation $\frac{1}{20}$th part of the alcoholic liquid, then beginning again with the original volume and collecting $\frac{2}{20}$, and, from a third distillation, $\frac{3}{20}$, the percentage of alcohol distilling over is in inverse ratio to the concentration of the liquid. For instance, in a mixture of alcohol and water, 1 : 500 – 1 : 1,000, the whole of the alcohol of the former is not over when one-third of the liquid has been drawn over; whereas when the concentration is below 1 : 3,000, the entire volume of the alcohol may safely be considered as contained when the distillate amounts to one-fourth the original quantity. The estimation can then be performed by the Nicloux bichromate method, by adding a solution of potassium bichromate (19 grammes per litre) and 4 or 5 c.c. of pure concentrated H_2SO_4, and comparing the resulting colour with standard colour samples containing known amounts of alcohol. C. S.

Estimation of the Higher Alcohols in Spirits. X. Rocques. (*Ann. de Chim. Analyt.*, vol. ii. [8], pp. 141-146.)—The method employed at the Paris Municipal Laboratory, which consists in heating the alcohol with sulphuric acid and determining the amount of coloration produced, may be rendered more accurate and delicate by the following modifications, in which the aldehydes are first fixed by the employment of an amine: 100 c.c. of the sample, previously distilled and adjusted so as to contain 50 per cent. of alcohol, are boiled gently for an hour with 2 grammes of metaphenylenediamine chloride and a few granules of pumice in a flask surmounted by a reflux condenser, and, after recooling, distilled. To prevent any spray passing over during distillation, the flask is set at an angle of about 45° and connected to a glass coil. Heat should be applied at a rate sufficient to complete the operation in forty minutes, and the condenser must be long enough (40 inches) to cool the distillate to the ordinary temperature. Seventy-five c.c. of the distillate are collected; this volume contains the whole of the alcohol, and consequently indicates 66·7 per cent. on the alcoholimeter.

To apply the sulphuric acid test, 10 c.c. of the distillate are pipetted into a 100 c.c. flask, and 10 c.c. of pure, colorless, monohydric sulphuric acid poured in down the side of the flask. The whole is shaken up and heated for an hour in a brine-bath boiling at 120° C.

A standard solution of 0·667 gramme of isobutylic alcohol per litre of 66·7 per cent. alcohol (*i.e.*, corresponding to 0·5 gramme per litre of 50 per cent. alcohol), is prepared and treated in the same manner, for the purpose of comparing the resulting colorations. This examination is made on the cooled liquids, in a Dubosc colorimeter, the amount of higher alcohols (per litre of 50 per cent. alcohol) in the sample being found and expressed as isobutylic alcohol by the aid of the formula $\frac{500 \times H}{H^1}$, wherein H = the stratum of the standard liquid and H^1 that of the sample. The depth of colour is not exactly proportional to the quantity of the higher alcohols present. The subjoined list shows the ratio between the apparent and actual amount:

Apparent.	Actual.	Apparent.	Actual.
1·125	1·000	0·379	0·400
1·009	0·900	0·255	0·300
0·886	0·800	0·150	0·200
0·760	0·700	0·060	0·100
0·640	0·600	0·019	0·050
0·500	0·500		

The delicacy of the reaction is nearly twice as great (100 : 55) with the above method, employing 66·7 per cent. alcohol, as in the ordinary method with 50 per cent. alcohol. In the colorimetric examination it is advisable to make several readings, *e.g.*, two with a 10 m.m. and two with a 20 m.m. stratum, and strike the mean of the results; the depth of the yellow tinge, with its green fluorescence, is readily appreciable, especially in a 10 m.m. stratum.

Should the proportion of higher alcohols exceed 1 gramme per litre of 50° alcohol—a rare occurrence in practice—the sample should be suitably diluted with pure 66·7 per cent. alcohol after, or by 50 per cent. alcohol before, being distilled. These standards must be accurately maintained, or the colorimetric results will be irregular; but when carried out as prescribed, the method will give comparable and constant, though not absolute, figures. C. S.

On the Occurrence of Alcohol in Milk. H. Weller. (*Forsch. Ber.*, 1897, iv., 206.)—The examination of a sample of milk which had been complained of by the consumer as leaving an unpleasant after-taste gave the following results:

Specific gravity at 15° C.	1·0335.
Fat	3·89 per cent.
Total solids	13·307 ,,
Alcohol (by weight)	0·96 ,,

The milk was derived from a considerable number of cows which were fed on distillery slummage containing 5·90 per cent. of alcohol.

The substance which caused the unpleasant taste could be expelled from the

milk in a current of steam, and separated from the distillate in fine flakes. Its amount was very small. It could also be isolated from the slummage in a similar manner.

From this instance, the author considers that the statement of König (*Nahr. und Genussmittel*, 1893, 249), that when cattle are fed upon fodder containing alcohol the latter does not pass into the milk, is disproved. C. A. M.

Detection of Margarine in Cheese. H. Bremer. (*Forsch. Ber.*, 1897, 51-53.)—By extracting the fat from the cheese with ether, the author considers that impurities are simultaneously extracted, and in Henzold's method, in which the fat is extracted by means of 5 per cent. potash, all the free fatty acids, as well as those in combination with ammonia, are saponified. The method considered the most satisfactory is to shake the finely-divided cheese with water at 20° to 30°, acidified with sulphuric acid (5 : 200), and to apply centrifugal force, when the fat rises to the surface, whilst the albuminoid substances coagulate at the bottom.

In addition to the determination of the usual constants, valuable information may be obtained from the iodine value of the "liquid" fatty acids. In a number of experiments with pure butter-fat, this iodine value did not exceed 95, even when the cows had been fed on maize oil-cake. A sample of Edam cheese yielded a fat, the liquid fatty acids of which had an iodine value of 93·35, whilst the values obtained with two samples of margarine cheese (Rodam and Backstein) were 110·3 and 109·0 respectively. C. A. M.

The Examination of American Lard. Dr. von Raumer. (*Zeit. angew. Chem.*, 1897, 210-215 and 247-254.)—The continually increasing importation to Europe of American lards having high iodine values has made it necessary to alter the generally accepted limit for that value. The usual physical constants all show so much variation in genuine lard that, in the author's opinion, too much reliance must not be placed on them, while he distrusts Becchi's and Welmann's tests.

Schiff's reagent, however, appears to be capable of distinguishing between rancid and over-heated lards and those adulterated with cotton-seed oil, all of which will reduce the silver solution and give the green colour with the molybdic solution. Five c.c. of the melted fat are shaken with 10 c.c. of the reagent and placed in water at 90° C. for two or three minutes. In the author's experiments fresh lard either gave no colour at all or at most a faint rose, which disappeared in about thirty minutes when cold; slightly rancid lards gave a strong colour, which disappeared more slowly, and strongly rancid and over-heated lards gave a pronounced violet, which did not disappear on cooling. On the other hand, beef stearin and beef stearin containing 30 to 40 per cent. of cotton-seed oil showed no coloration.

The iodine number of the fat and of the so-called liquid fatty acids is considered by the author to be the most reliable test for lard. Attempts were made to concentrate the liquid acids by crystallization from amyl alcohol at 0° and 4° C., but this only raised the iodine value of the soluble portion by about 20. A modification of Muter and De Koningh's lead oleate method (ANALYST, xiv., p. 61) was therefore adopted. From the examination of a large number of samples, it was found that the iodine value of the liquid fatty acids of German lards seldom exceeded 94, the highest being 96·2. The highest figures obtained with American lards of undoubted purity were 66 and 104 for the fat and fatty acids respectively. C. A. M.

A New Method of Determining Caffeine in Coffee. E. Tassily. (*Bull. Soc. Chim.*, 1897, 766-768.)—The powdered coffee is digested with successive portions of boiling water, a litre of liquid being obtained from 10 grammes. The solution is divided into two parts, each representing 5 grammes. These are evaporated to dryness on the water-bath, the residue treated with 1 to 2 c.c. of sulphuric acid (1 : 10), and taken up with boiling water. The caffeine can then be extracted with cold chloroform from the solution made alkaline with ammonia, or with hot chloroform from the residue obtained on evaporating the aqueous solution with sand and magnesia. The former method gives slightly higher results, but in each instance the figures agree well with those obtained by other processes. C. A. M.

Modification of the Thalleioquin Test for Quinine. F. S. Hyde. (*Jour. Amer. Chem. Soc.*, 1897, xix., 331, 332.)—By substituting a clear filtered solution of calcium hypochlorite (bleaching powder) for the bromine or chlorine water the test is rendered more certain, and the green colour more brilliant. After acidulating the

quinine solution with one drop of sulphuric acid (1 : 4), the hypochlorite solution is added until the blue fluorescence just disappears and the solution acquires a faint golden tint. On now adding a few drops of dilute ammonia (1 : 3), a clear emerald green colour should appear. Potassium or sodium hypobromite cannot be used, as the strong alkali tends to precipitate the quinine. C. A. M.

ORGANIC ANALYSIS.

Colour Reactions of Aldehydes and Ketones. (*Zeit. anal. Chem.*, 1897, xxxvi., 369-376.)—Aldehydes and ketones give colour reactions with green fluorescence with the salts of any of the meta-diamines and also with the salts of the ortho- and paradiamines, but without the intense fluorescence. In making the test, a 0·5 to 1·0 per cent. aqueous or alcoholic solution of the chloride of a meta-diamine is added to the aqueous or alcoholic solution of the substance to be tested. The reaction takes place in a few minutes, and reaches its greatest intensity in about two hours. The liquid becomes colorless on the addition of alkali, but the colour is restored on adding acid. Mineral acids weaken the reaction.

The author's experiments indicate that the reaction always occurs when the carbonyl group is not united with a completely substituted hydrocarbon group.

The following table shows the reactions given by various aldehydes and ketones with meta-phenylene-diamine hydrochloride :

Aldehydes of the Fatty Series.

Formaldehyde, H.CHO, bright citron yellow
Acetaldehyde, $CH_3.CHO$, bright yellowish red
Monochlor-acetaldehyde, $CH_2Cl.CHO$, yellow
Isobutylic aldehyde, $(CH_3)_2 : CH.CHO$, bright orange yellow
Valeric aldehyde, $CH_3.(CH_2)_3.CHO$,, ,, ,,
Croton aldehyde, $CH_3.CH : CH.CHO$, brown red
Tiglic aldehyde, $CH_3.CH : C(CH_3).CHO$, brown red
Methyl-ethyl acrolein, $C_2H_5.CH : C(CH_3).CHO$, bright orange yellow
Aldol, $CH_3CH(OH).CH_2.CHO$, bright orange yellow
Furfural, $C_4H_3O.CHO$, bright orange yellow
Glyoxal, CHO.CHO, yellow, fluorescence after one to two hours

Aromatic Aldehydes.

Benzaldehyde, $C_6H_5.CHO$, bright citron yellow
p.-Cuminic aldehyde, $C_6H_4\langle^{C_3H_7}_{CHO}$, bright orange yellow
Anisaldehyde, $C_6H_4\langle^{O.CH_3}_{CHO}$, orange yellow.
o.-oxybenzaldehyde, $C_6H_4\langle^{OH}_{CHO}$, citron yellow

With green fluorescence.

Ketones.

Acetone, $CH_3.CO.CH_3$, yellow red
Mono-chlor-acetone, $CH_2Cl.CO.CH_3$, yellow red
Di-ethyl ketone, $C_2H_5.CO.C_2H_5$, violet red
Methyl propyl ketone, $CH_3.CO.C_3H_7$, brown yellow
Methyl hexyl ketone, $CH_3.CO.C_6H_{13}$, faint green
Methyl nonyl ketone, $CH_3.CO.C_9H_{19}$, brownish yellow

Reactions are not obtained with the following substances:

(*a*) *Aldehydes of the Fatty Series.*—Chloral, butylchloral, paraldehyde, aldehyde ammonia, sulphaldehyde $\left(S\begin{matrix}CH(CH_3).S\\CH(CH_3).S\end{matrix}CH.CH_3\right)$.

(*b*) *Aromatic Aldehydes.*—Nitro-phthal-aldehyde, vanillin.

(*c*) *Ketones.*—Acetophenone, mono-brom-acetophenone, benzylidine-acetone, benzo-phenone, naphthyl-phenyl-ketone, trioxy-benzophenone, benzoin, phenyl-thionyl-ketone.

The author has also examined the behaviour of Schiff's reagent, and finds that, contrary to the experience of others, it cannot be relied upon when used with a hot solution, since the reagent by itself always shows a distinct bluish-violet colour when cooled after having been boiled; and hence the appearance of a faint colour after boiling cannot be taken as conclusive of the presence of aldehydes or ketones.

On the other hand, a solution of grape-sugar boiled with the reagent and cooled gives no coloration, and from this the author confirms Nickel's observation that grape-sugar exercises a disturbing influence. C. A. M.

On the Determination of Copper as Oxide in the Gravimetric Estimation of Sugar. K. Farnsteiner. (*Forsch. Ber.*, 1897, iv., 169-171.)—The author defends his method (ANALYST, xx., 258) from certain criticisms of Bremer as to its accuracy (*Forsch. Ber.*, 1897, 110), and describes experiments by different chemists with the object of proving that the variations in the reduction method are just as great as in his oxidation process.

In working the reduction method, he has obtained most satisfactory results by substituting methyl alcohol for hydrogen. A moderate stream of dried carbon dioxide is passed through methyl alcohol at the ordinary temperature and then through the tube, which requires rather more heating than when hydrogen is used. When reduction is complete, the tube is allowed to cool in a current of carbon dioxide.

C. A. M.

An Iodometric Method of Estimating Sugar. G. Romijn. (*Zeit. anal. Chem.*, 1897, xxxvi., 349-359.)—When glucose in alkaline solution is acted upon by iodine, gluconic acid is produced in accordance with the equation

$$CH_2OH.(CHOH)_4.CHO + 2I + 3NaOH = CH_2OH.(CHOH)_4.COONa + 2NaI + 2H_2O;$$

but where caustic alkali is used, the gluconic acid is liable to undergo further decomposition. When the caustic alkali is replaced by certain alkaline salts, the results are much more in accordance with theory, and of these salts the most suitable is borax. The temperature, quantity of sugar, and time of action must all be taken into account.

The sugar solution (about 10 c.c.) is placed in a stoppered flask with 25 c.c. of iodine solution, containing 1 gramme of borax and as much iodine as requires, after the addition of acid, from 30 c.c. to 33 c.c. of decinormal thiosulphate for decolorization. The flask is then maintained at 25° C. by means of a thermostat for the

required time, at the end of which 1·5 c.c. of hydrochloric acid (specific gravity 1·126) is added, and the excess of iodine titrated with decinormal thiosulphate.

The results obtained with glucose solutions when the volume of the mixed solutions was 35 c.c. to 50 c.c., the time sixteen to twenty-two hours, and the amount of glucose 154 to 164 milligrammes, showed 97·76 to 99·47 per cent. of the theoretical quantity. With further dilution the results were too high, owing to the hydrolytic dissociation of the borax.

Similar experiments were made with solutions of fructose, which was hardly attacked at all, the figures indicating only about 3 per cent. of the amount taken.

A few of the results obtained with pure specimens of other sugars are given below. In each case 2 atoms of iodine were taken as equivalent to 1 molecule of the sugar. It is noticeable that the aldoses—galactose, mannose, arabinose, xylose, and rhamnose—behaved in the main like glucose.

Sugar.	Quantity in milligrammes.	Hours.	Milligrammes found.	Per cent.
Galactose	169·3	20	171·92	101·55
Mannose	166·4	18½	168·94	101·53
,, ...	155·2	18½	161·89	104·31
Arabinose	149·4	18	144·53	96·75
Xylose	142·7	18½	143·79	100·76
Rhamnose	37·1	18	41·72	112·45
,, ...	146·2	18	145·69	99·65
Chitosamin – HCl .	187·4	18½	199·72	106·56
Sorbose	166·3	18½	4·43	2·66
Maltose	338·4	20	351·94	103·71
Lactose	150·35	17½	169·46	112·72
,, ...	333·55	18	349·04	104·65
Saccharose	334·72	17½	50·67	15·14
,, ...	334·72	17½	51·01	15·24
Raffinose	298·1	18½	122·61	41·13
,, ...	504·5	18½	161·95	32·10
Stachyose	318·6	18½	133·11	41·78

Where the results are too high (*e.g.*, maltose and lactose), it is only necessary to increase the quantity of the sugar taken to obtain the correct amount.

The paper also contains an account of some experiments on other substances. Ethyl alcohol, acetone, and formic acid exercised a strong reducing action on the borax iodine solution; glycerin, lactic acid, and mannite did the same, but in a much less marked degree; whilst acetaldehyde and tartaric acid were practically without action on it. With regard to the determination of mixtures, the author gives a long table in which it is proved that a mixture of glucose and fructose may be estimated as though pure glucose. Thus, 153·78 milligrammes of glucose with 80 milligrammes of fructose yielded 154·21 milligrammes = 100·28 per cent. of glucose. Mixtures of lactose and saccharose gave results about 6 per cent. too high, whilst those obtained with a solution containing glucose and mannite were about 20 per cent. too low. In mixtures of cane-sugar and lactose the figures, which were constant in duplicate determinations, were about 5 per cent. too high.

The author's general conclusion is that this method promises an accurate means of determining aldoses by themselves and in the presence of ketoses and other substances, but that it is not always applicable in practice. C. A. M.

The Insoluble Carbohydrates of Wheat. H. C. Sherman. (*Journ. Amer. Chem. Soc.*, 1897, xix., 291-316.)—I. DESCRIPTIVE.—It is shown that the hemicellulose of wheat apparently yields only pentoses on hydrolysis, and therefore consists of pentose anhydrides, or true pentosans.

The fibre left after treatment with sulphuric acid yields furfural, gives the magenta colour (produced by lignin) on treatment with chlorine and boiling with sodium sulphite, and the red colour characteristic of pentosans with phloroglucinol. When immersed in a solution containing molecular proportions of ferric chloride and potassium ferricyanide it fixes a certain amount of the ferricyanide—a reaction shown by Cross and Bevan to be characteristic of lignocellulose, of which jute is the type.

Lignone chloride ($C_{19}H_{18}Cl_{14}O_9$) isolated by Cross and Bevan from chlorinated jute-fibre, was also obtained from wheat, and it is suggested that this type of lignification may be common in plants of annual growth.

The furfural-producing constituents are the hemicellulose, and bodies in combination in the lignin group (about 40 per cent.), and in the cellulose obtained by the chlorination method (about 10 per cent.); but in the case of wheat these are all of a pentosan nature. The author considers it advisable to distinguish between these, and to group them into those dissolved readily by dilute acids (pentosans proper) and those which resist acid or both acid and alkalies (combined pentosans).

II. ANALYTICAL.—The following scheme gives an outline of the method of analysis proposed. Five grammes of the sample (previously extracted with ether) are stirred with 100 c.c. water for a few minutes, filtered, and washed.

FILTRATE.—Boiled with $\frac{1}{10}$ its volume of 25 per cent. HCl, clarified, and dextrose determined with Fehling's solution in an aliquot portion. Result calculated to	RESIDUE.—Treated with malt-extract till starch disappears, cooled, filtered, and washed.			
	FILTRATE.—treated as in the case of preceding filtrate. Dextrose found calculated to	RESIDUE.—Boiled thirty minutes with H_2SO_4 (1·25 per cent.), filtered, washed with water and alcohol.		
		FILTRATE.—H_2SO_4 to make 2 per cent. added. Boiled under reflux condenser six hours. Reducing power determined and calculated to pentose and thence to	RESIDUE.—Dried and weighed, proteid and ash determined in duplicate residue, and correction made. Treated according to method of Cross and Bevan, dried, and residue weighed.	
			Loss of weight corrected for proteids and ash equals	RESIDUE, less proteid (if present), and ash equals
Soluble carbohydrates as dextrin.	Starch.	Free pentosans.	Lignin and allied substances.	Cellulose.

Starch.—Reference is made to a previous paper by the author (see ANALYST, this vol., 19.), in which the superiority of the malt-extract method over other methods is proved.

True Pentosans.—Sulphuric acid was chosen, as it was found to cause but little alteration in the pentosans even on long boiling. The copper reduced was determined by Allihn's method, and the pentose taken as 97 per cent. of the indicated dextrose. Pentose × 0·88 = pentosan.

Cellulose.—Comparative experiments were made with three methods:

(1) Schulze's method—digesting substance with nitric acid and potassium chlorate, and subsequently washing with 2 per cent. ammonia.

(2) Cross and Bevan's method, in which 30 grammes of fibre are boiled for thirty minutes with 800 c.c. of 1 per cent. sodium hydrate, well washed, squeezed as free from water as possible, and subjected to the action of chlorine for an hour, with occasional stirring. The mass is then filtered, washed free from acid, heated to boiling with 600 c.c. of 2 per cent. sodium sulphite, and sufficient sodium hydrate solution added to make $\frac{1}{5}$ per cent. of the whole. After being boiled for five minutes the solution is filtered hot through a muslin filter, washed till neutral and colorless with water, then washed with alcohol, dried and weighed.

(3) Lange's method—fusion with alkali (ANALYST, xx., 283).

The results obtained by the three methods, as also by exposure to chlorine, wet, and without treatment with alkali, showed the superiority of Cross and Bevan's method.

	Description of Product.				
Method	Yield per cent.	Furfural per cent.	Nitrogen per cent.	Ferricyanide fixed, per cent.	Colour.
Cross and Bevan ...	66·5	5·62	0·00	9·20	Light cream.
Schulze	66·0	7·00	0·22	6·04	Light brown.
Lange	41·2	3·96	0·03	0·89	Nearly white.
Chlorination alone ...	84·3	8·89	0·08	2·02	Very light brown.
Original sample ...	100·0	11·46	0·25	11·17	

Determination of Furfural.—For this a modification of the method of the Association of Official Agricultural Chemists is used. From 2 to 5 grammes are distilled with 100 c.c. of hydrochloric acid (specific gravity 1·06), each 30 c.c. passing over being replaced by the hydrochloric acid, and the distillation continued until the distillate gives no red colour with aniline acetate. The distillate is made up to 400 c.c., and for each 50 c.c. of water used 10·2 grammes of sodium chloride are added. The liquid is exactly neutralized with sodium carbonate, and 10 c.c. of a solution of phenylhydrazine acetate added. This is prepared by mixing 12 grammes of phenylhydrazine with 7·5 grammes of glacial acetic acid and diluting to 100 c.c. After being well stirred for thirty minutes the whole is kept in the dark until next day. The precipitate is collected on a glass-wool filter, and dried to constant weight at 55° to 60° in a slow current of air. It is then dissolved off the filter with alcohol, the filter-tube dried and weighed, and the loss of weight calculated as furfural hydrazone. From the result the pentosans can be calculated by the factors

Hydrazone × 0·516 + 0·0104 = furfural.
Furfural × 1·84 = pentosans.

III. Physiological.—The author was fortunately able to obtain samples of the food and fæces of a steer, which was being fed for experimental purposes on wheat-bran only, and to ascertain the digestibility of each of the constituents as determined by this method. The following are the results calculated on the dry substance:

	Food per cent.	Fæces per cent.	Per cent. digested.
Soluble carbohydrates as dextrin	7·2	0·7	96·9
Starch	17·7	0·0	100·0
Free pentosans	17·5	18·7	66·2
Cellulose	8·5	20·2	24 8
Lignin and allied substances	11·6	23·2	36·7
Protein	20·49	11·04	82·96
Ether extract	6·92	12·52	42·73
Ash	6·05	11·04	42·21
Undetermined	4·04	2·60	...
Nitrogen-free extract...	55·59	41·93	76·08
Crude fibre	10·96	23·47	32·21

The total dry matter digested was 68·33 per cent. of the whole. These figures prove that the digestibility of the insoluble carbohydrates ranges from 25 to 100 per cent., and since there is also a possible difference in the physiological value of the digested portions, a distinction between starch and pentosans should always be made in food analysis. While the normal carbohydrates are known to be completely digested in the healthy body, it has been held that lignin is but little oxidized, and supplies directly the benzol radicle in the hippuric acid in the urine of herbivorous animals (Stutzer, *Ber.*, viii., 575; Weiske, *Zeit. Biol.*, xii., 24). With regard to the pentoses and pentosans authorities differ. Ebstein (*Arch. path. Anat.*, cxxix., 401) came to the conclusion that they were practically without nutritive value. Salkowski (*Cent. med. Wissen.*, 1893, 193) and Cramer (*Zeit. Biol.*, xix., 484) found that they were digested for the most part, the latter holding that they caused an increased storage of glycogen in the liver. On the other hand, Fretzel (*Archiv. ges. Physiol.*, lvi., 273), from experiments on rabbits with xylose, concluded that in no way did this sugar contribute to the formation of glycogen. C. A. M.

Estimation of Glycerol. C. Böttinger. (*Chem. Zeit.*, 1897, xxi., 658.)—The author has attempted to work out a process based on the conversion of the glycerol into its triacetic ester by means of potassium bisulphate and acetic anhydride. Under the conditions detailed in the paper he has succeeded in obtaining from commercial glycerin dehydrated at 170° C. a fairly uniform yield, averaging in twelve experiments 151·4 per cent. (maximum 157·4 per cent., minimum 143·6 per cent.), whereas theory demands 237 per cent.

As regards methods depending on the treatment of alcoholic wine extracts with ether, he finds on acetylating the different products (1) that nearly half such an extract is soluble in the ethereal liquid, (2) that the soluble portion is by no means pure glycerol, but may contain 43 per cent. of other substances, and (3) that the undissolved part of the extract may retain even more glycerol than is actually taken up by the ether. F. H. L.

The Analysis of Commercial Xylidine. W. Vaubel. (*Zeit. anal. Chem.*, 1897, xxxvi., 285-289.)—Commercial xylidine usually contains the five isomerides—α-and-β-ortho-xylidine, α-and-β-meta-xylidine, and para-xylidine, of which the chief are the α-meta compound, or asymmetric meta-xylidine and para-xylidine.

To determine the amount of the former, advantage is taken of the fact that its acetate and chloride are insoluble in acetic acid and hydrochloric acid respectively, the most satisfactory results being obtained with acetic acid. A hundred grammes of the substance are mixed with 100 grammes of glacial acetic acid, and after twenty-four hours the precipitate is filtered off with the aid of a suction-pump, air-dried, and weighed. It consists for the most part of the acetate of asymmetric meta-xylidine, but is liable to contain a small amount of the acetyl derivative, or of the acetate of one or more of the other isomerides.

On treatment with a solution of bromine in hot sodium hydrate the two meta-xylidines absorb 1 atom of bromine, as do also their acetyl derivatives, whilst the other isomerides absorb 2 atoms. But as the acetate of β-meta-xylidine is very soluble in acetic acid, only traces of it can occur in the precipitate.

The amount of the acetyl derivative in the precipitate can be determined by the rate at which the bromine is absorbed, for it absorbs its 1 atom of bromine much more slowly than does the salt. It is best to hydrolyse it before the titration by boiling for ten minutes with hydrochloric acid.

In illustration of the method, the following results of the analyses of a technical xylidine are given :

Specific gravity at 20° C. = 0·982

Fractional distillation (750 m.m.)	210°	211°	212°	213°	214°	215°	residue
Per cent.	14	18	18	24	6	2	2

A hundred grammes of the xylidine, mixed with 100 grammes of glacial acetic acid, yielded 32 grammes of solid acetate, corresponding to 20·8 per cent. of α-meta-xylidine. But on treatment with the bromine solution, it was found that about half of the precipitate consisted of the acetyl derivative. The bromine required for 16 grammes of acetate = 7·1 grammes, and for 16 grammes of the acetyl derivative = 7·8 grammes—together = 14·9 grammes. But the actual amount of bromine absorbed was 17·9 grammes; therefore the 20·8 grammes of precipitate contained 3·5 grammes of the acetate of ortho- or of para- xylidine, since these can absorb 2 atoms of bromine.

C. A. M.

Colour Reactions of Nitric and Chloric Acids with Certain Aromatic Bodies. E. C. Woodruff. (*Journ. Amer. Chem. Soc.*, 1897, xix., 156-169.)—This paper gives the particulars of upwards of 300 reactions of different inorganic salts, with the various types of aromatic substances. In general, chloric acid produces a darker colour than nitric acid, and although many of the tests will detect them separately, in most cases, when mixed, the effect of the nitrate is completely masked.

A modification of the phenol test for nitrates is suggested; it is said to be more delicate than the usual test. One c.c. of concentrated sulphuric acid is placed in a test-tube, and on it is floated a layer of not more than 0·5 c.c. of a saturated aqueous solution of phenol. A drop of the unknown solution is now allowed to fall upon the

upper layer, generally producing a brown ring. After standing for some time the whole is shaken and neutralized, when a picrate-coloured solution indicates a nitrate. Chlorates produce a brownish-yellow, instead of a greenish-yellow, colour.

Diphenylamine (4 per cent. solution) is a delicate test for nitrates, but has the disadvantages that it will not keep well in solution, that it is not possible to dilute or neutralize it so as to eliminate the effects of bromides and iodides, that nitrates, chlorates, bromates, and iodates all give practically the same colour with it, and that it must be kept cool. The most satisfactory reagent for detecting nitrates in the presence of chlorates and other inorganic salts is a mixture of dimethylaniline (2 drops), and paratoluidine (0·2 gramme) in sulphuric acid (10 c.c.). This gives a blood-red colour with nitrates if the chlorate is not present in too great excess.

Two methods of removing or reducing the strength of chlorates found satisfactory are:

(1) The solution is acidified with sulphuric acid and boiled, after the addition of hydrochloric acid, until on adding another drop of hydrochloric acid no yellow colour appears. The phenol test will now show the nitrates without the slightest trace of brown due to the chlorate.

(2) The solution is evaporated just to dryness, and water added in sufficient quantity to dissolve the nitrate, but not all the chlorate, which is much less soluble. The solution is decanted, diluted, and examined by the dimethylaniline test.

But the best method of applying the test is to add to the unknown solution a little potassium chlorate, if not already present, and then to boil with hydrochloric acid. This oxidizes all reducing agents that might interfere with the test without introducing enough chlorate to mask the nitrate reaction. C. A. M.

Examination of Sumach. M. Spica. (*Gazz. Chim. Ital.*, 1897, xxvii., 349; through *Chem. Zeit. Rep.*, 1897, 173.)—Sumach is frequently adulterated with the leaves of *Tamarix Africana* (Sicilian "bruca,") or of *Pistacia lentiscus* ("stinco"). Five grammes of the samples are boiled for half an hour in 500 c.c. of water, the loss by evaporation made up and the decoction filtered. Twenty-five c.c. are shaken with 5 c.c. of a solution containing 250 grammes of basic lead acetate in 1 litre of water (specific gravity 1·184) and 15 c.c. of caustic potash (specific gravity 1·155), and the mixture concentrated to a volume of 15 c.c. The liquid should be quite clear, any precipitate indicating impurity or adulteration. It is then diluted to 250 c.c., filtered, and examined colorimetrically, when the depth of tint should be equal to that of a solution of 0·15 gramme of safranine in 1 litre of water; any foreign matter causes the liquid to be paler in shade.

The nitrogen in sumach is 0·912 per cent., in tamarix 1·77 per cent., and in pistacia 1·63 per cent.; while the amounts of ash are 6·60, 12·40 and 5·40 per cent. respectively. F. H. L.

Betanaphthalenesulphonic Acid as a Reagent for Albumin, Albumoses and Peptones. E. Riegler. (*Pharm. Central H.*, 1897, xxxviii., 379; through *Chem. Zeit. Rep.*, 1897, 173.)—Five or six c.c. of the liquid under examination are mixed in a test-tube with 20 or 30 drops of a filtered 5 per cent. solution of β-naphthalene-

sulphonic acid in water. One part of albumin in 40,000 of water gives a noticeable precipitate which does not disappear on heating. Albumoses and peptones yield precipitates which dissolve on warming, but reappear when the liquid becomes cold again. F. H. L.

Analysis of Commercial Albumin. P. Carles. (*Jour. Pharm. Chim.*, 1897, 102-104.)—It is not uncommon to find samples of albumin containing from 12 to 25 per cent. of insoluble coagulated matter without the power of fining wine, whilst others contain gum, dextrin, or gelatin.

Two grammes of a preparation are treated with distilled water up to 200 c.c. If the albumin is free from coagulated matter, the solution is quite transparent. To 100 c.c. of the solution, 35 c.c. of a 1 per cent. of *pure* tannin are added, and about 0·2 gramme of powdered potassium bitartrate. The liquid is well shaken, and a small portion filtered. One portion of the filtrate is tested for excess of tannin, and to another portion several drops of the tannin solution are added.

If tannin be found, it proves that of the 0·35 gramme added originally, part has not been taken up by the albumin, which is accordingly deficient in true albumin, and contains either inert substances, fraudulently added, or overheated portions.

If, on the other hand, the addition of more tannin solution causes a turbidity, the inference is that the albumin contains a substance precipitable by tannin, and which has for tannin a greater saturation capacity than the albumin itself. All the gelatins have the property of precipitating about four times as much tannin as desiccated albumin.

As a further test, 100 c.c. of the solution are warmed on the water-bath in order to coagulate all the albumin present. After filtration of a heated solution of pure albumin, no further precipitate with tannin is obtained, whereas there is an abundant one when gelatin is present. In the same filtered liquid, dextrin, gums, and other substances, if present, may be detected by the usual methods. C. A. M.

Estimation of Gelatin. P. Carles. (*Ann. de Chim. Analyt.*, vol. ii. [10], pp. 181, 182.)—The author believes that the method proposed by Jean (*Analyst*, this volume, p. 164), though excellent for a gelatin liquor of uniform character, and one wherein all the glue constituents are completely gelatinized, would give rise to error if used on a bouillon in course of manufacture, owing to the differences in the time of boiling necessary for the conversion of the various albuminoids, as well as to the differences in the properties of the resulting products.

The precipitating action of the commercial gelatins on pure tannin is very divergent, 10 grammes of Russian fish-glue, dissolved at 40° C., throwing down 4 grammes of tannin, whilst the same quantity of granulated extra gelatin precipitates 8 grammes; cut fish-glue from 3 to 10 grammes (according to the state of division or solution); bone-gelatin and brown Givet glue 11 grammes; Bordeaux gelatin 11·50 grammes; and Laîné gelatin 12·50 grammes of tannin. C. S.

Optical Analysis of Urine, Positive and Negative Thermo-optical Diabetic Sugar. Fr. Landolph. (*Rev. de Chim. Analyt. Appl.*, vol. v. [14], pp. 278, 279.)—

Thermo-optically Positive (true diabetic) Sugar.—The principal characteristics of this sugar are: stability, rapidity of fermentation—about thirty minutes at 15° C. and under—and high reducing power, the latter being double that of grape sugar, *i.e.*, 100 grammes correspond to 441 grammes of copper oxide. When examined by the polaristrobometer at the ordinary temperature, and again after boiling, the optical power is found to increase, *i.e.*, the sugar is thermo-optically positive. The results of this examination agree with those obtained by determining the carbon dioxide evolved during fermentation; but the reduction method with Fehling's solution is inaccurate, being based on the erroneous assumption that this sugar has the same reducing power as grape sugar. The precipitate of hydrated cuprous oxide formed by diabetic sugar is yellow and more voluminous than the anhydrous red oxide thrown down by grape sugar, uric acid, etc., but the latter oxide is sometimes furnished by diabetic urines that have undergone transformation.

Thermo-optically Negative Sugar.—This always accompanies diabetic sugar, but, like grape sugar, loses its positive rotatory power when boiled. It ferments more slowly than true diabetic sugar, and is generally found anterior to diabetes. The author has frequently examined urines exhibiting a dextrorotation of several degrees and shown, both by fermentation and by the polaristrobometer, to contain sugar, but which on boiling gave only the normal levo-rotation due to free uric acid and urates.

C. S.

Rapid Estimation of Uric Acid in Urine. E. H. Bartley. (*Jour. Amer. Chem. Soc.*, 1897, xix., 649-656.)—The method is based on the complete precipitation of uric acid by silver nitrate in the presence of excess of magnesia mixture and ammonia, the end-point being detected by an alkaline sulphide. The precipitation of the xanthine bases by the silver nitrate is obviated by titrating in a hot solution.

To 50 or 100 c.c. of clear urine are added 5 c.c. of magnesia mixture and about 10 c.c. of ammonium hydrate (specific gravity, 0·960). After warming the mixture on the water-bath, $\frac{1}{60}$ N. silver nitrate is run in, until a drop removed by means of a pipette with cotton tied over the end, to act as a filter, gives a dark coloration when brought into contact with a weak solution of sodium sulphide. Experiments with pure water showed that 0·5 c.c. of the silver solution in 50 c.c. was required to give a marked reading, and this amount must therefore be deducted from the reading.

Each c.c. of silver nitrate corresponds to 0·00336 gramme of uric acid, and from the number of c.c. used (less 0·5 c.c. for each 50 c.c. of urine), the amount of uric acid can be calculated.

If, after the titration is complete, the solution is cooled, an addition of 1 to 3 c.c. of the silver solution will be required to again produce the end-reaction, the xanthine bases being precipitated by the silver in a cold solution.

The results obtained in this way, as compared with Ludwig's method, which has been proved to give too low results, were:

C. A. M.

Lintner's Reaction of Guaiacum with Diastase. **B. Pawlewski.** (*Ber.*, 1897, xxx., 1813.)—The blue colour produced by an alcoholic solution of guaiacum mixed with hydrogen peroxide in presence of active diastase is only characteristic of the latter if the reaction occurs instantaneously, and if there is no other body at hand capable of acting in a similar manner. Should the colour only appear after a few minutes the test is valueless, for many substances will determine it; in fact, guaiacum tincture gives a blue colour with hydrogen peroxide alone, especially on warming.

F. H. L.

Improvements in Ultimate Organic Analysis. **M. Dennstedt.** (*Ber.*, 1897, xxx., 1590.)—This process effects the simultaneous estimation of N, S, and Cl (or other halogen), as well as the C and H in any organic body. The combustion tube is about 83 cm. long, open at both ends, and is heated by a number of flat-flame burners rather than in the ordinary furnace. At the centre it contains a layer 6 or 8 cm. long of platinum black, prepared by igniting some such compound as the chloroplatinate of pyridine, which, provided a proper current of oxygen is constantly maintained, need only be raised to a dull red heat to ensure complete oxidation. At the further end of the tube the usual apparatus for absorbing the water and the carbon dioxide are provided.

If the substance contains nitrogen, NO_2 is produced, and this is absorbed as such in two boats filled with lead peroxide placed in the tube behind the platinum black, and heated to about 150° by means of a special burner, the boats being weighed before and after the operation. If the body contains only Cl,* two boats of precipitated silver are employed at a temperature of 200° or 300°, and weighed as above. If N, as well as Cl, is present, both the lead and the silver boats are inserted in the tube; but only the latter require weighing. If the substance contains only S,* all four boats are used, and all must be weighed. The greater part—often the whole—of the sulphur is oxidized to sulphuric acid, and is directly absorbed by the silver; some is only burnt to sulphurous acid, and is taken up by the lead as SO_2. In presence of both S and N, the contents of the lead boats are extracted with 33 per cent. alcohol, and a portion of the filtrate evaporated to give the amount of lead nitrate formed; this is calculated into NO_2, when the remainder of the increase in weight represents the SO_2. If both S and Cl occur, the silver chloride and sulphate are separated by being dissolved in potassium cyanide, filtered, the HCN displaced by HCl, the silver chloride removed, and the sulphuric acid in the filtrate precipitated with barium. The weight of the SO_4 so obtained, deducted from the total gain of the silver boats, gives the amount of halogen. In the event of N, Cl, and S being all present, the lead oxide boats absorb the N as NO_2 and $\frac{1}{2}$ or $\frac{1}{3}$ of the S as SO_2, and the silver boats take up the Cl or other halogen and the remainder of the S as SO_4.

The author states that the results are quite accurate, and he appends the figures derived from the actual analysis of parabromphenylthiourea, which agree well with those demanded by theory.

F. H. L

* Beside the C, H, and O.

Yellow Light for Saccharimeters. F. Dupont. (*Rev. de Chim. Analyt. Appl.*, vol. v. [10], p. 186.)—The author finds that a fused mixture of chloride and tribasic phosphate of sodium in about molecular proportions furnishes a salt which fuses more readily than the chloride, and does not decrepitate, thus giving a steadier and clearer flame than that obtained with sodium chloride alone. C. S.

INORGANIC ANALYSIS.

The Separation of Molybdenum and Tungsten. E. D. Desi. (*Jour. Amer. Chem. Soc.*, 1897, xix., 242.)—At the conclusion of a long communication on the oxides of tungsten, the author refers to the methods of separating molybdenum and tungsten. Rose's method, in which the molybdenum is precipitated from the mixed solution as sulphide by adding tartaric acid and passing in hydrogen sulphide to saturation was shown by Friedheim and Muller (*Zeit. anorg. Chem.*, i., 76) to be not quite satisfactory, a small quantity of molybdenum always remaining in solution. The fact that tungstic acid is completely insoluble in concentrated or dilute sulphuric acid, hot or cold, whereas molybdenum trioxide is readily soluble, affords a simple and exact method of separating the two elements. C. A. M.

Separation of Nickel from Cobalt, Nickel from Iron, and Cobalt from Aluminium. E. Pinérua. (*Ann. de Chim. Analyt.*, vol. ii. [11], pp. 201, 202.)—The method proposed is based on the insolubility of the chlorides of nickel and aluminium in ether saturated with hydrochloric acid, in which reagent cobalt and iron are readily soluble. The metallic chlorides in question are dissolved in a small quantity of water, and after adding 10 to 12 c.c. of fuming hydrochloric acid and 10 c.c. of (preferably anhydrous) ether the liquid is agitated and saturated with gaseous hydrochloric acid at a low temperature. Nickel is thrown down as a heavy crystalline yellow chloride which is washed on the filter with ether saturated with gaseous hydrochloric acid, and the metal determined by any of the usual methods, *e.g.*, as sulphate. If iron be present along with cobalt the filtrate will be greenish-blue or yellow-green.

Aluminium and cobalt are separated in the same way, the former being precipitated as chloride. In separating nickel from iron the nickel precipitate must be repeatedly washed with ether, and, if necessary, redissolved and the operation repeated.

From the behaviour of the commercial chlorides of nickel and cobalt in presence of solvents the author shares the belief of Winckler and others that these metals are unknown in a pure state, but probably contain hitherto unidentified elements.

C. S.

Separation of Iron and Alumina by the Aid of Sodium Peroxide. C. Glaser. (*Chem. Zeit.*, 1897, xxi., 678.)—The solution is nearly neutralized with ammonia and dry sodium peroxide (2 to 3 grammes of Na_2O_2 to 0·4 gramme of substance) added until the liquid becomes clear and all the iron is converted into ferrate. The whole

is boiled, allowed to settle, and filtered. The precipitate of ferric hydrate is dissolved in acid and thrown down again by means of ammonium sulphide from a solution containing ammonium citrate or tartrate; while the filtrate is acidified and the alumina determined by phosphoric acid and ammonia acetate, or any of the usual methods.

The original liquid should be freed from silica, and although the iron precipitate does not carry down any phosphoric acid with it, but is contaminated merely with adhering alkali, any considerable amount of calcium phosphate should be removed with ammonium acetate or by Glaser's process before the addition of the sodium peroxide. F. H. L.

The Determination of Sulphur in Pig-iron. A. A. Blair. (*Jour. Amer. Chem. Soc.*, 1897, xix., 114, 115.)—The author's experiments prove that sulphur may be present in pig-iron in four forms: (1) Sulphur evolved as hydrogen sulphide on dissolving the iron in hydrochloric acid; (2) Sulphur evolved as other compounds, not absorbed by alkaline lead-salts or oxidized by bromine or potassium permanganate; (3) Sulphur unacted on by boiling hydrochloric acid, but oxidized by nitric acid or *aqua regia*; (4) Sulphur unacted on by nitric acid, hydrochloric acid, or *aqua regia*.

Bamber's method (*Jour. Iron and Steel Inst.*, 1894, i., 319) is recommended for treatment of pig-irons containing sulphur in the last form. Five grammes are dissolved in strong nitric acid, 2 to 5 grammes of potassium nitrate added, and the solution evaporated to dryness in a platinum capsule and ignited. The residue is treated with water containing a little sodium carbonate, filtered, and the filter washed also with water containing sodium carbonate. The solution is acidulated with hydrochloric acid, evaporated to dryness, redissolved in water containing a few drops of hydrochloric acid, brought to the boil, and the sulphur precipitated with barium chloride. C. A. M.

The Composition of Red Lead. D. Woodman. (*Jour. Amer. Chem. Soc.*, 1897, xix., 339-341.)—For certain purposes, it is important to know the degree of oxidation in specimens of red lead, and this the author determines by digesting the red lead in a saturated solution of normal lead acetate, which dissolves the litharge in excess of that in combination as Pb_3O_4. In this way a series of results was obtained showing a variation in the amount of actual red lead of from 41 to 92 per cent. The small amounts of silica, lime, oxide of iron, and carbon dioxide normal in the commercial article are neglected:

Red lead ...	Pb_3O_4	51·0	56·0	75·0	41·0	90·0	66·0	87·5
Litharge ...	PbO	49·0	44·0	25·0	59·0	10·0	34·0	12·5

The author quotes from Gmelin the figures showing the amount of red lead formed from massicot. One firing of twenty-four hours in a reverberatory furnace yielded 50·0 per cent. of red lead; two firings yielded 52·1; five firings, 66·2 per cent.; and eight firings, 74·8 per cent. Red lead from "white lead," after three firings of twenty-four hours each, contained 95·3 per cent. Hence these results seem to show that there has been little or no improvement in the methods of manufacture, at least as regards more complete oxidation. C. A. M.

APPARATUS.

A New Hot-Water Oven for Temperatures over 100° C. F. Gantter. (*Forsch. Ber.*, 1897, iv., 154, 155.)—This is a double-walled oven with an opening for a thermometer. The jacket is filled full of water, and the outlet through which steam usually escapes is connected with a barometer tube containing mercury. By regulating the gas-flame any temperature, from 100° to 110° or higher, corresponding to the pressure, may easily be maintained. Near the bottom of the oven there is a safety-valve. C. A. M.

REVIEW.

THE ANALYST'S LABORATORY COMPANION. BY ALFRED E. JOHNSON, A.R.C.S.I., F.I.C. Second edition (J. and A. Churchill). Price 5s.

This admirable and handy little volume, which contains all the tables usually required by analysts, has been carefully revised and has now reached its second edition. A new table of five-figure logarithms takes the place of the former seven-figured one, a saving of time being effected by its use without the sacrifice of too much accuracy. The section on weights and measures has been entirely re-written, and the tables dealing with the specific rotatory and reducing powers of the carbohydrates extended in the light of recent research. The nitrogen to albuminoid matter table has been re-calculated on the basis of the more modern factor 6·25 instead of the older one of 6·33. A new and useful table for calculating c.cs. of pentinormal acid into their equivalents of nitrogen, for use in the Kjeldahl process, has been introduced. Improvements have been made in the alkali tables, and also some new and useful matter inserted in connection with alcohol estimation. These are *some* of the novelties and improvements met with, and they serve to show that the work has been fully brought up to date. The little useful facts and hints interspersed throughout the work constitute not the least valuable portion of it. Blank pages are also interleaved, on which the user may make his own personal notes. Altogether, the book is of such a useful and time-saving nature that no busy analyst can afford to be without it.

W. J. S.

CORRESPONDENCE.

ASBÓTH'S PROCESS FOR THE ANALYSIS OF BUTTER.

To the Editor of THE ANALYST.

DEAR SIR,—This, which is recorded on page 213 of your issue for August last, though excellent is not novel, a similar process having been described by West-Knights (ANALYST, vol. v., p. 155), the only difference being the employment of a lime salt instead of a lead one.

The process for estimating oleic acid is substantially that described in THE ANALYST, vol. xiv., p. 61, the only modification being that the lead salts are precipitated in a cold solution, as was proposed by myself in the *Nederl. Tydschr. v. Pharm., etc.*, 1890, p. 26.

Yours, etc.,

L. DE KONINGH.

THE ANALYST.

NOVEMBER, 1897.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

DERBY MEETING.

A COUNTRY meeting of the Society was held at Derby on Friday, October 8.

In the morning a visit was paid to the locomotive works and also to the carriage works of the Midland Railway Company, as well as to the excellently-appointed laboratory of Mr. Archbutt, the chemist to the company. Before proceeding to inspect the works, the members had a cordial reception from Mr. S. W. Johnson, the locomotive superintendent of the Midland Railway, who spoke in appreciative terms of the services rendered to railway engineers by the chemical profession.

After lunch, visits were paid to the printing and lithographic works of Messrs. Bemrose and Sons, and to the works of the Crown Derby Porcelain Company.

In the evening the members dined together at the Midland Railway Hotel. Amongst the visitors present were Professor Clowes, president of the Society of Chemical Industry, Mr. James, of the Midland Railway Company, and Dr. Iliffe, medical officer of health to the Corporation of Derby. The president of the Society (Dr. Dyer) referred to the disappointment experienced by all public analysts at the meagre and unsatisfactory nature of the Adulteration Bill introduced to Parliament towards the close of last session by the president and secretary of the Local Government Board, and expressed the hope that every public analyst would impress upon his County Council or local authority the shortcomings of that Bill, in order that, in the interests of the public, such authorities might take steps to endeavour to induce the Government to introduce a better measure, which should really embody, instead of overlooking, the chief recommendations of the Select Committee. Cordial thanks were expressed to Mr. Archbutt and to Mr. White (public analyst for the county of Derby) for the trouble they had taken in organizing a pleasant and successful gathering.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

The Detection of Formalin in Milk by Means of Phloroglucinol. M. Jorissen. (*Service de Surveillance des Aliments en Belgique*; through *Bull. Soc. Chim.*, 1897, 167.)—Several drops of a 10 per cent. aqueous solution of phloroglucinol are added to about 10 c.c. of the milk, the mixture shaken, and a few drops of a solution of caustic soda or potash added. A red coloration is produced with milk containing as little as 1 part of formalin in 20,000, whilst normal milk gives no reaction.

C. A. M.

Proportion of Mineral Matters and Earthy Phosphates in Cows' Milk. L. Vaudin. (*Ann. de Chim. Analyt.*, ii. [18], 344-347.)—From analyses of the milk from several different breeds of cows fed on a variety of fodder, the author concludes that in normal milk the percentage of mineral matter (ash) ranges within the limits of 7 and 8 grammes per litre, of which 3·3 to 4 grammes consist of earthy phosphates (lime, magnesia and iron), precipitable by ammonia. This is independent of breed, soil, daily yield, etc., but the individuality of the animal and the diet exercise a slight influence on the proportions between the above limits. On the other hand, in milk rendered abnormal by pathological or other influences, the percentage of ash and proteid bodies is increased, but in an irregular manner. For example, in the case of a pregnant cow the milk contained 52·16 per cent. of albuminoids and 8·6 per cent. of ash, and that from one poisoned by oil-cake infested with aspergillus, 44·0 and 8·5 per cent. respectively, whereas the albuminoids in two instances of normal milk amounted to only 36·3 and 41·6 per cent.

C. S.

Determination of Boric Acid in Meat Products. C. Fresenius and G. Popp. (*Zeit. für öffent. Chemie*, iii., 188.)—10 grammes of chopped meat or sausage-meat are rubbed up in a mortar with four to eight times the quantity of calcined sodium sulphate. The mortar with its contents is then placed in a water-bath for about an hour, and, as soon as the mass is dry, some more sodium sulphate is added and the whole ground to a fine powder. This is then digested in 100 c.c. of cold methyl alcohol for twelve hours, with frequent shaking, after which the alcohol is distilled off. Though, as a rule, the boric acid passes over completely in one distillation, it is recommended to extract the residue a second time, using 50 c.c. methyl alcohol. The distillate is made up to 150 c.c. with methyl alcohol, and the boric acid determined in 50 c.c. by titration as follows: The 50 c.c. are mixed with 75 c.c. of water, and 25 c.c. of pure glycerin. The whole is well mixed, and then titrated with $\frac{N}{20}$ soda solution (free from carbonic acid) using phenol-phthalein as indicator. A pale rose colour denotes the end of the reaction. When this appears, more glycerin solution is added, and if the colour does not stand, the titration is continued

further. The number of c.c. of soda used multiplied by 0·0031 gives the boric acid (H_3BO_3) in the titrated quantity of distillate.

Should the sample contain borates as well as boric acid, they would remain in the residue left from the distillation. As most borates (and especially sodium borate) are soluble in methyl alcohol, they can be extracted by this means from the mass, and determined in the evaporated residue, after incineration, by the method of Hönig and Spitz.

The following results show the accuracy of the method:

0·4038	gramme	boric acid	in 10	grammes	chopped meat	yielded 0·4093 gramme.
0·4034	,,	,,	,,	,,	,,	0·4030 ,,
0·4212	,,	,,	,,	,,	,,	0·4264 ,,

H. H. B. S.

On Wine-Glycerin. R. Kayser. (*Zeit. für öffent. Chemie*, iii., 190.)—As is well known, the glycerin extracted from wines is always in a very impure state. The author examined the glycerin extracted from a white wine by the process given in the memorandum of the German Imperial Chancellor, of June 25, 1896, and found that it contained in round numbers about 20 per cent. of foreign substance.

H. H. B. S.

New Method of Estimating Tartaric Acid in Wine. L. Briand. (*Ann. de Chim. Analyt.*, ii. [17], 321.)—The author proposes to add to the wine (50 c.c.) an excess of pure potassium sulphate crystals, shaking up briskly, and leaving for two days in a cool place. After filtering, the residue is carefully washed with dilute alcohol (15 per cent.), saturated with both potassium sulphate and bitartrate. The correction to be added for the solubility of the bitartrate in the wine after the above treatment is 0·35 gramme per litre. By this means the free tartaric acid present is obtained as bitartrate in addition to that existing in a ready-formed condition in the wine. The results are very concordant, and the other constituents of the liquid do not exert any appreciable influence on the solubility of the precipitate. C. S.

Estimation of Potassium Bitartrate in Wines. H. Jay. (*Ann. de Chim. Analyt.*, ii. [14], 264-267.)—From investigations performed on wines and several other alcoholic liquids containing potassium bitartrate, to compare the accuracy of the Berthelot and Fleurieu (direct precipitation) and Reboul (evaporation) methods, the author concludes that the higher results furnished by the latter are due to a disturbance of the natural equilibrium of the various acids and salts in the liquids in question. The result of this action is that potassium bimalate crystallizes out along with the bitartrate, and gives results in excess of the truth. The error may be demonstrated by evaporating down to 100 c.c. different volumes of liquid containing bitartrate, the results becoming excessive when the reduction in volume is greater than 5 : 1. Consequently he considers the direct precipitation method to be, though inexact, nearer and more regularly approximate to the truth than that of Reboul. The correction found necessary to make good the deficiency in the results of the first-

named method was determined, from liquids containing 1·35 to 2·72 grammes of bitartrate, to be between 0·19 and 0·22 gramme. C. S.

Estimation of Potassium Bitartrate and Free Tartaric Acid in Wines. L. Magnier de la Source. (*Ann. de Chim. Analyt.*, ii. [15], 281-283.)—Referring to the paper by H. Jay (see previous abstract), the author remarks that the error due to potassium bimalate in the Reboul and similar methods may also be occasioned by free malic, tartaric and lactic acids, œnolic acids, and acid salts. This will be greater in proportion to the suddenness with which the evaporated wine, etc., is cooled, but is reduced, by his own method (ANALYST, this volume, p. 217) of slow evaporation at the ordinary temperature.

When the presence of free tartaric acid is suspected, sufficient potassium hydrate should be added to neutralize about one-fifth of the total acidity before concentrating the liquid. A check experiment, without addition of potassium hydrate, will show whether an excess of tartaric acid is present. In this approximate test for the free acid, the best washing liquid is dilute alcohol (30 to 35 per cent.), the bitartrate crystals being but very slightly soluble therein; but for the accurate estimation of the total acid when the wine has been partly saturated by potassium hydrate the solution of potassium bitartrate and sulphate (*l.c.*) is preferable. C. S.

Earth Nut-Oil. S. P. Sadtler. (*Amer. Jour. Pharm.*, 1897, lxix., 490-492.)—Owing to the more extended use of earth nut-meal, the expression of the oil is now undertaken on a commercial scale. The author considers that when freed from the free acid present in the raw state it does not tend to become rancid so readily as olive-oil, and that there is no reason why it should not be used in pharmacy where that oil is now used, the products being equally good, whilst the cost is much less. It is stated that the bulk of Castile soap manufactured in Marseilles at the present day is made from African earth nut-oil.

The cold pressed oil is of a pale, yellow colour. About 38 per cent. was obtained from the Virginian earth nuts, and nearly 10 per cent. more by a second hot-pressing. The following table gives the results of the analyses of oil derived from various sources:

	Oil from Virginia Nuts.	Oil from Spanish Nuts.	Oil from African Nuts.	Oil from Puducheri.	Commercial Oil.

C. A. M.

Colorimetric Determination of Aymi and Isobutyl Alcohols. X. Rocques. (*Ann. de Chim. Analyt.*, ii. [12], 221, 222.)—In the case of wine-brandies, and similar liquids wherein amyl alcohol constitutes the major part of the higher alcohols present, it would be more logical to express the results obtained by the author's colorimetric method of estimation (ANALYST, vol xxii., p. 263) as amyl alcohol. To this end he has plotted curves of the data obtained for amyl and isobutyl alcohols under identical conditions, from which it appears that their colorimetric ratio is ordinarily about 6 : 10. In a 50% wine-brandy containing a quantity of higher alcohols expressed by 1 gramme of isobutylic alcohol, according to the aforesaid method, the actual quantity of amyl alcohol present would be over 1·5 gramme. Bearing this in mind, it is unnecessary to alter the type of comparison in use, since that course would lead to a confusion in the results obtained by different workers.

C. S.

On the Determination of the Caramel on Coffee-berries roasted with Sugar. W. Fresenius and L. Grünhut. (*Zeit. anal. Chem.*, 1897, xxxvi., 225-233.)—The different methods used in this determination all consist in treating the entire berries with a solvent for a certain time.

König's Method.—Ten grammes are twice shaken for five minutes with 200 c.c. of boiling water. Each time the solution is decanted and the berries finally washed with 100 c.c. When cool, the solution is made up to 500 c.c. and filtered. An aliquot part of the filtrate is evaporated, the residue dried at 100°, weighed, and the ash determined and deducted.

Neubauer's Method.—Ten grammes of the berries are moistened with ether, and then treated for fifteen minutes with 400 c.c. of boiling water, with frequent shaking. The solution and washings are made up to 500 c.c., filtered, and the caramel determined as in König's method.

Stutzer's Method.—Ten grammes are shaken in a shaking machine for five minutes, with 250 c.c. of cold water. The liquid (containing the berries) is made up to 500 c.c., filtered, and an aliquot part of the filtrate treated as above. This is the method adopted by the Association of Bavarian Chemists.

Hilger's Method.—Ten grammes are shaken for half an hour each time with three successive portions of 100 c.c. of dilute alcohol (equal parts of water and 90 per cent., by volume, alcohol). The united solutions are made up to 500 c.c., filtered, and the residue and ash determined as in the other methods.

The authors point out that it is necessary to decant the liquid from the berries before filtering, since the extra time considerably increases the relative amount of ash in the extract, which is to be attributed to more of the constituents of the berry being extracted.

These methods were tried on four different kinds of coffee which had been roasted, alone and with the addition of sugar in two proportions. The percentage of residue yielded to the solvents when the berries were roasted alone in the normal manner (*i.e.*, with about 18 per cent. loss) was :

I.

Coffee.	Containing Ash.				Ash-free.			
	König.	Neubauer.	Hilger.	Stutzer.	König.	Neubauer.	Hilger.	Stutzer.
Yellow Java	2·45	2·49	0·92	0·77	1·91	1·75	0·71	0·60
Green Java	3·22	2·32	0·87	1·06	2·38	1·65	0·62	0·73
Blue Java	3·47	2·74	1·81	0·46	2·52	1·97	1·39	0·42
Maracaibo	3·77	2·49	0·66	0·46	2·56	1·83	0·60	0·33

Deducting these values from the total amount of residue obtained when the same coffees had been roasted with sugar, the following amounts of caramel were left:

II.

Coffee.	Sugar added. Per cent.	Containing Ash.				Ash-free.			
		König.	Neubauer.	Hilger.	Stutzer.	König.	Neubauer.	Hilger.	Stutzer.
Yellow Java ...	7½	3·64	2·30	2·46	2·07	2·98	2·01	2·33	1·66
	9	3·82	2·34	2·95	1·35	3·33	2·38	2·95	1·18
Green Java ...	7½	0·95	2·43	2·31	0·38	1·07	2·27	2·27	0·58
	9	4·30	4·24	3·65	1·47	4·17	4·08	3·67	1·54
Blue Java ...	7½	1·79	2·57	1·86	1 16	2·00	2·49	1·99	1·09
	9	3·75	4·76	3·72	2·40	3·57	4·19	3·44	1·04
Maracaibo ...	7½	3·47	3·88	3·29	1·28	3·04	3·24	3·01	1·08
	9	3·99	4·93	4·07	1·87	4·07	4·50	3·62	1·70

These results show that the amount of caramel obtained by Stutzer's method is altogether too low if a deduction is made for the substances extracted from the coffee-berry itself. The other methods show an approximate agreement, but when they differ, that of Hilger usually agrees with one or the other. This fact, and also that the amount of ash passing into solution when the berries roasted without sugar are treated by the different methods is considerably less by Hilger's process than in the methods of König and Neubauer, have led the authors to give the preference to the former. They consider that the most accurate course is to make a determination by Hilger's method, and to deduct from the result a mean constant for the substances in the berries themselves which have dissolved with the caramel. The figures thus obtained, together with those from Stutzer's method (without deduction) are shown below.

C. A. M.

The Alterations produced in Coffee on Roasting. A. Hilger and A. Juckenack. (*Forsch. Ber.*, 1897, iv., 119-135.)—The authors have studied the alterations which take place when coffee is roasted in the usual manner, and after the addition of 8 to 9 per cent. of sugar, according to a German patent. The chief results of their experiments, summarized, are :

1. *Caffeine.*—In the ordinary process of roasting, coffee loses about 21 per cent. of its caffeine, and about twice as much when it is roasted with sugar. This is to be explained by the fact that the sugar is added with the object of glazing the coffee, and that for this purpose it is necessary to caramelize it, which requires a much higher temperature than is reached in the usual method of roasting.

2. *Fat.*—The loss of fat in the ordinary roasting is from 9 to 10 per cent. In the glazing process it amounts to about 20 per cent. As a rule, the different constants of the fat showed an increase on roasting, both in the ordinary way and with the addition of sugar.

3. *Organic Matter.*—In the author's experiments, coffee lost in the mean 11·375 per cent. of organic matter on roasting, and about 10 per cent. in the glazing process, allowance being made in the latter case for the amount of caramel produced. The amount of caramel on the glazed coffee was determined by Stutzer's method. Twenty grammes of the glazed beans were shaken in a machine for five minutes with 500 grammes of water at 20° C. The liquid was filtered, 250 c.c. of the filtrate evaporated to dryness in a platinum dish, and the residue dried and weighed. From the weight obtained the weight of ash was deducted. In this way on coffee glazed with 9 per cent. of sugar there was found 1·40 per cent. of caramel, as against 1·25 per cent. in a sample of Java coffee glazed with 8 per cent. of sugar (*cf.* ANALYST, xx., 249), and the preceding abstract. C. A. M.

A Method of Collecting and Analysing the Gases in Damaged Canned Goods. C. A. Doremus. (*Jour. Amer. Chem. Soc.*, 1897, xix., 733-735.)—A hollow, bevelled, steel needle is fixed in the upper arm of an adjustable clamp, with its point passing through the hole of a rubber cork which rests upon the top of the can. The upper part of the needle is connected by means of a capillary tube with a gas burette or nitrometer filled with water or mercury. The can, which is held between the lower arm of the clamp and the rubber cork, is then punctured by turning the lower screw until the needle pierces the top. The rubber cork makes a tight joint round the needle, and the gases escape gently into the eudiometer, where they are measured and analysed in the usual way. From 60 to 80 c.c. of the gas can often be collected.

When there is a putrid odour, carbon dioxide forms the chief constituent of the mixed gases. In other cases hydrogen predominates, there is no offensive smell, and bacteria are absent, whilst there are indications of the corrosion of the inner metallic surface. Hydrogen has also been found without distinctive signs of corrosion. Occasionally the can is discolored, as though traces of sulphuretted hydrogen had been formed, and reactions of the metals may be obtained with the contents of such tins. C. A. M.

On the Amount of Iron in the Ashes of certain Plants. B. Niederstadt. (*Forsch. Ber.*, 1897, iv., 140.)—This paper gives the figures recently obtained by the author in his analysis of various vegetable products used as food. The amount of iron (as Fe_2O_3) contained in twenty-six samples of American apple cuttings varied from 0·009 to 0·046 per cent., but, as these had all been cut with a steel knife, it was possible that some of the iron might have been derived from the knife.

The mean percentage of ash in the specimens of malt examined was 2·5, and the iron oxide ranged from 0·25 to 0·91 per cent. In unroasted coffee-berries of various origin, Liebig found from 0·019 to 0·044 per cent. of iron oxide, whilst the author's analyses of seventeen samples gave as a rule considerably higher results, the raw berries containing from 0·35 to 0·88 per cent., and the roasted berries from 0·07 to 0·65 per cent. C. A. M.

A Method of Drying Sensitive Organic Substances. C. C. Parsons. (*Jour. Amer. Chem. Soc.*, 1897, xix., 388, 389.)—The process consists in expelling the moisture by putting the substance directly into hot mineral oil. The best results were obtained by the author with a perfectly neutral paraffin oil, of specific gravity 0·920, 435° flash test, 500° fire test, and about 550° boiling-point. The object of a high fire test is that the oil shall be free from volatile matter which would escape with the moisture.

The oil is prepared by heating it to about 250° for some time and keeping it in a closed vessel. The substance to be dried is divided into thin small pieces, weighed, and placed with about six times its weight of oil in an evaporating dish. The dish and oil which have been previously heated to 240°, are, after the addition of the substance, maintained at that temperature for a few minutes after effervescence has ceased. The difference between the weight of the dish and oil plus the substance before the

drying, and of the dish and its contents after drying, gives the moisture. Ordinarily the whole operation may be completed in twenty minutes.

Very satisfactory results have been obtained with soap and wood pulp, and since the substance is perfectly protected from the action of the air by being immersed in the oil, it should be possible to use the process in the case of many substances which cannot be dried in the ordinary way. C. A. M.

Application of Hydrogen Peroxide to the Analysis of Food Stuffs. Lebbin. (*Pharm. Zeit.*, xvii., 1897; through *Deutsche Chem. Zeit.*, 1897, 205.)—This reagent possesses in a high degree the property of converting starch into soluble modifications, and can consequently be employed in all those cases where it is necessary to remove starch from other tissues. If so much potato-starch is added to a solution of hydrogen peroxide as would with a similar quantity of water yield a thin paste, the mixture brought to the boil, and a few drops of ammonia added, considerable frothing ensues, and a clear solution results almost instantaneously. If the solution is immediately neutralized and tested with iodine, the blue colour shows that the action has only proceeded as far as soluble starch; if, however, the solution is boiled for some time, it yields with this reagent the brown-red colour indicative of erythrodextrin. Estimation of the starch dissolved in this way does not, so far, appear to have been attended with entirely satisfactory results; but the process is peculiarly applicable to those cases where the starch-free residue has to be submitted to microscopical examination, since the microscopical appearance of the cellulose structures is entirely unaltered. The author has found the method serviceable in differentiating wheat-flour from rye-flour, also in detecting ergot in flour. W. J. S.

A New Method for Isolating Deutero-albumose. Sigmund Fränkel. (*Monatsheft f. Chemie*, 1897, 433.)—In order to obviate the difficulty of removing large quantities of sodium chloride or ammonium sulphate by dialysis, and to avoid the actual loss of substance entailed in the separation, both of which are inherent in the process proposed for this purpose by Kühne and improved by Neumeister, the author proposes to make use of cupric sulphate. This reagent, though it does not cause the slightest turbidity in solutions of pure deutero-albumose, gives, according to Neumeister, a voluminous precipitate with solutions of 1:500, and a turbidity with solutions of 1:1,000 of deutero-albumose contaminated with proto-albumose. Experiments were conducted with Witte's salt-free peptone, with Finzelburg's albumin- and meat-peptone, and also with pepsin- and trypsin-peptones of the author's own preparation.

A dilute solution of cupric sulphate was added to the solution of the peptone, when a tough coherent precipitate formed, leaving a turbidity which generally disappeared after a few hours' standing. Attempts to separate the copper from the solution by hydrogen sulphide or magnesium failed, but success was attained with barium ferrocyanide. A hot saturated solution of this salt was added until a filtered portion of the proteose solution only showed traces of copper. Before absolutely the

whole of the copper was removed, the mixture was acidulated with acetic acid, warmed, filtered, and the filtrate washed. Solution of barium ferrocyanide was then added drop by drop to the warm filtrate as long as a red precipitate formed; then barium acetate to remove sulphuric acid. By practice it was found easy to hit the exact point when all the cupric sulphate was removed. The solution, after being evaporated to a small bulk, was poured into strong alcohol, dehydrated with absolute alcohol, and washed with ether.

Deutero-proteose prepared in this way gives no turbidity or precipitate with sodium chloride alone, but on the addition of acetic acid partial precipitation ensues; ammonium sulphate also yields an abundant precipitate. It gives neither turbidity nor precipitate with potassium ferrocyanide and acetic acid, nor with copper sulphate, and is therefore free from proto-albumose. Experiment showed that the method was suitable for the isolation of the deutero-albumose obtained in trypsin digestions.

W. J. S.

Examination of Mace. P. Soltsien. (*Zeit. für öffent. Chemie*, iii., 253.)—Attention is called to the difference between Bombay and Banda mace as regards the quantity of matter extracted by ether, after removal of the fat by petroleum spirit, and it is suggested that advantage should be taken of this fact, in order to distinguish between the two. The difference is very considerable, the quantity being about ten times as great with Bombay mace as with true mace. The author has never found more than 4·8 per cent. of matter extracted by ether in a pure Banda mace, and proposes that 5·5 per cent. should be fixed as a safe maximum.

The manipulation is carried out as follows: 10 grammes of powdered mace are exhausted by boiling petroleum spirit in an extraction apparatus. On cooling, an oily portion tends to separate at the bottom of the vessel, and this belongs properly to the extractive matter soluble in ether. The petroleum spirit extract is poured off, the separated oily portion in the flask washed with petroleum spirit and dissolved in absolute ether, and then a second extraction is made with boiling ether. In the ether extract there is also a tendency for a portion to separate out. The extract is poured off, the separated matter washed with ether, and the washings added to the extract, which is then filtered, evaporated, and dried in the water-bath, the residue being weighed.

H. H. B. S.

On Clove-Oil. E. Erdmann. (*Jour. prak. Chem.*, 1897, lvi., 143-156.)—Thom's method of valuing clove-oil (*Verhand. der Gesell. deutsch. Naturf.*, 1891, 184) consists in determining the amount of eugenol after converting it into benzoyl eugenol. The author points out that this is based on the assumption that only free eugenol is present, and proves that by previous complete saponification higher results are obtained owing to the presence of aceteugenol, which he finds to be a constituent of the higher-boiling fractions of clove-oil. After the determination of the eugenol by Thom's method, a further estimation should be made in the following manner: 5 grammes of the clove-oil are saponified by heating over a naked flame for three minutes with 11 grammes of soda lye (29 per cent. NaOH). Alcoholic potash must not be used, or the results will be too low on account of the formation of esters.

After saponification 10 c.c. of water are added, and the estimation completed as in Thom's method. In this way the following percentages of eugenol were obtained:

	Thom's Method.	Total Eugenol.
Clove-oil A ...	... 83·9 ...	... 85·68
B ...	... 82·97 / 82·77 ...	... 84·84
C ...	... 80·2 ...	... 81·9

The difference between the results of the first and second estimations corresponds to a percentage of from 2·1 to 2·6 of aceteugenol. Specimens of clove-stalk-oil were found to contain no aceteugenol, and this appears to be a point of difference between the two oils.

Among other substances found in clove-oil were salicylic acid (which was probably present as acetyl-salicylic acid in combination with the eugenol) and furfural. The latter was extracted from the oil, and also identified by the xylidine reaction (*Ber.* xx., 540). The vapour from the heated oil is brought into contact with filter-paper moistened with a mixture of *m*-xylidine and glacial acetic acid, or with aniline acetate. A still more sensitive reaction for furfural is given by a solution of 5 grammes of β-naphthylamine in 20 c.c. of acetic acid, several drops of which are placed on filter-paper, and a drop of the solution to be tested then added. Strong furfural solutions give an intense purple colour. Dilute aqueous solutions (1 : 10,000) show the reaction strongly, and it is still recognisable in solutions of 1 in 100,000. In this way furfural can be detected in cigar smoke. Both clove-oil and clove-stalk-oil give an intense purple colour.

Characteristic colours are given by other aldehydes with the reagent. Citral gives a reddish yellow; salicylic aldehyde and anisaldehyde a yellow; formaldehyde, propylaldehyde and valeric aldehyde, an extremely faint yellow; acetaldehyde and crotonaldehyde a somewhat stronger brownish yellow. A yellow colour is also obtained with eugenol. C. A. M.

TOXICOLOGICAL ANALYSIS.

The Destruction of Organic Matter in Toxicological Work. A. Villiers. (*Bull. Soc. Chim.*, 1897, 678.)—The substance is placed in a flask with a thistle funnel reaching nearly to the bottom, and a delivery tube passing into a vessel containing water, and is mixed with dilute hydrochloric acid (1 : 2 or 3). Several drops of a solution of a manganese salt and a little nitric acid are then introduced and the flask gently warmed. The gaseous products, consisting of carbon dioxide and nearly pure nitrogen, pass off very regularly, and there is no liberation of malodorous vapours. The operation is completed as in the ordinary chlorate method. Any residue left consists only of fatty matter which has been able to resist the oxidizing action. It is claimed that the method is much more easily carried out than oxidation by means of potassium chlorate and hydrochloric acid.

C. A. M.

ORGANIC ANALYSIS.

Examination of Bees-wax. **R. Henriques.** (*Zeit. für öffent. Chemie*, iii., 274.)—The author has examined Weinwurm's qualitative method for testing the purity of bees-wax (*cf.* ANALYST, this vol., 242). He reports favourably of the process, but proposes to simplify it by a modification, which was suggested by Leffmann and Beam's proposal for the saponification of butter by alkaline glycerin solution (*cf.* ANALYST, 1891, 153; 1892, 65).

The modified process is conducted as follows: A piece of wax about the size of a pea is boiled in a test-tube for three or four minutes with 5 c.c. of alkaline glycerin solution (25 c.c. soda solution of a specific gravity of 1·383 and 125 c.c. pure glycerin). The solution, which is at first quite clear, becomes gradually cloudy. After boiling for about the time mentioned, the oil collects to a layer, and the underlying fluid becomes clear. The bubbles of the boiling mass also now become smaller, and the glycerin commences to distil. As soon as this point is reached, the heating is discontinued. The fluid is now poured into another test-tube, in order to separate it from the unsaponified portion; an equal volume of hot water is added, and the fluid boiled and allowed to cool. In the case of pure wax, the solution will be now either quite clear and transparent, or, at any rate, sufficiently translucent to allow of large printed matter being read through it, as described by Weinwurm. Should, however, on the contrary, as much as 5 per cent. of foreign hydrocarbons be present, the fluid will be quite opaque. With an admixture of only 3 per cent. of ceresin or paraffin, the indication is uncertain, and the further procedure recommended by Weinwurm to meet such cases should be followed. H. H. B. S.

Determination of Paraffin in the Distillates from Lignite, Tar, and Crude Petroleum. **D. Holde.** (*Zeit. angew. Chem.*, 1897, 116, 117.)—The author has confirmed Aisinman's statement as to the comparative insolubility in alcohol of the distillates of high boiling-point from crude petroleum. Thus, from 1 to 1½ litres of alcohol were required to dissolve from 10 to 20 grammes of different Russian oils, whilst at the same time a considerable amount of paraffin also dissolved, and the separated paraffin required a great deal of washing to free it from the adhering oil. It was found that a litre of absolute alcohol dissolved 0·3 gramme of paraffin at 0° C.

The method proposed by Grotowsky, and modified by Engler and Böhm, was found to give the most satisfactory results. The oil is dissolved in as little ether as possible, and the paraffin precipitated with alcohol at a temperature of −18° to −20° C., and washed on a double filter with as little as possible of a mixture of ether and alcohol. During the washing the same low temperature is maintained, and the work is done as rapidly as possible in order to prevent the paraffin dissolving. From one to two hours is required for a complete estimation. Test analyses of mixtures of oil and paraffin gave results in close accordance with theory, and duplicate analyses of the distillates of various lubricating-oil distillates agreed well with each other. C. A. M.

The Normal Urine. **C. Platt.** (*Jour. Amer. Chem. Soc.*, 1897, xix., 382, 383.)—For several years the author has kept the records of all urine analyses, with due regard to the age, sex, and health of the individuals, and his figures, in all cases compared, and in some averaged, with those of foreign observers (of whom fifty-two are named), are given in the table below.

The normal urine is of a pale amber or straw colour. It is clear or has a faint cloud of mucus, and has an "aromatic" odour. The reaction is acid, the acidity in twenty-four hours being equivalent to 2 to 4 grammes of oxalic acid. The specific gravity at 15° C. ranges for adults from 1·015 to 1·025, the average for man being 1·020, and for woman 1·018. The quantity in twenty-four hours varies from 1,100 to 1,600 c.c., with an average for man of 1,450 c.c. (22 c.c. per kilo of body weight), and for woman of 1,250 c.c.

C. A. M.

Testing Commercial Albumin. P. Carles. (*Ann. de Chim. Analyt.*, ii. [13], 241).—To examine commercial albumin for impurities, 2 grammes are gradually thinned down with water, and finally made up to 200 c.c., the solution being clear in the absence of coagulum due to over-heating in the manufacture. 100 c.c. are taken and shaken up briskly with 35 c.c. of a 1 per cent. solution of pure tannin and 0·20 gramme of powdered potassium bi-tartrate. Ten to 15 grammes of the turbid liquid are passed through a filter, and the clear filtrate divided equally, a few drops of a 0·5 per cent. solution of pure (Grénet's) gelatin (10 c.c. corresponding to 0·10 of a commercially pure tannin) being added to one portion, and a similar quantity of 1 per cent. tannin to the other.

If both solutions remain clear, then the sample is free from extraneous or coagulated matter. If, however, the gelatin solution produces a precipitate, it is evident that the tannin solution was in excess, and that therefore the albumin is poor and adulterated, the amount of adulteration being indicated by the volume of gelatin solution required to precipitate the tannin. On the other hand, a turbidity in the second portion of the filtrate indicates the presence of a substance (*i.e.*, gelatin), precipitable by tannin, and having a higher coefficient of saturation by that reagent than is possessed by albumin.

The second 100 c.c. can then be freed from albumin by boiling, and any gelatin present thrown down by tannin. Any gums or dextrins employed as adulterants can be separated from the residual liquid by strong alcohol after concentration, and can be estimated in the ordinary manner. C. S.

INORGANIC ANALYSIS.

The Volumetric Determination of Lead. J. H. Wainwright. (*Jour. Amer. Chem. Soc.*, 1897, xix., 389-393.)—This is a modification of the process described in Crookes' "Select Methods," which the author found the most satisfactory of various volumetric methods tried, although it was necessary to alter some of the details before he could obtain concordant results. From 1 to 1·5 grammes of the ore are

dissolved in 10 to 15 c.c. of nitric acid (specific gravity 1·20), the solution neutralized with ammonia in excess, and a considerable excess of acetic acid added. It is then boiled, and potassium bichromate solution in sufficient quantity to precipitate nearly all the lead is run in from a burette. The liquid is boiled until the precipitate becomes orange coloured, after which the titration is finished, the final point being indicated by means of silver nitrate as an outside indicator. The bichromate solution should be standardized on the pure metal, or by means of pure white lead in which the metal has been determined gravimetrically. One c.c. should equal about 0·01 gramme of lead.

The precautions to be observed are:

The solution of the lead salt must be as concentrated as possible, and decidedly acid with acetic acid. There must be absence of other metals, especially such as can exist in lower forms of oxidation. Antimony and tin, unless thoroughly oxidized, and bismuth are particularly to be avoided. During titration the solution should be kept as near the boiling-point as possible. The strength of the bichromate solution should not vary much from that given above, and the test solution of silver nitrate should be dilute, not over 2 to 3 per cent.

The method is specially suitable for such substances as white lead, red lead, litharge, etc. Red lead is dissolved by treating it with nitric acid, and adding a dilute solution of oxalic acid drop by drop until the lead oxide is completely dissolved. If organic matter is present the solution should be filtered before titration. White lead can be dissolved directly in acetic acid, and the solution titrated without filtration. In the case of white lead ground in oil, the sample should be dissolved in dilute nitric acid, the solution boiled, filtered, neutralized with ammonia in excess, and an excess of acetic acid added. The method can also be used with lead bullion, and alloys containing tin and antimony, but the sample must be thoroughly oxidized by repeated evaporation with fuming nitric acid, and the solution filtered before titration.

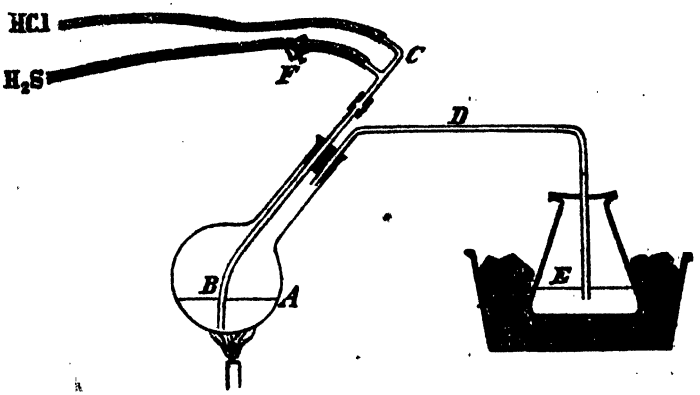
The results tabulated by the author are concordant, and in close agreement with those required by theory. C. A. M.

The Electrolytic Determination of Cadmium. S. Avery and B. Dales. (*Jour. Amer. Chem. Soc.*, 1897, xix., 379-382.)—Precipitation from a cyanide solution was found the most satisfactory when more than 0·1 gramme of the metal was present (solution 150-200 c.c., and area of electrode for plating 100-150 square cm.), but a strong current was necessary, and the last traces of metal were hard to precipitate. A solution containing 0·0452 gramme of cadmium in the cyanide solution was placed in a current from a thermopile for twenty-four hours. The thermopile had a tension of 4 volts, and an ampèrage of 2, with no resistance other than the ampèremeter. The quantity of cadmium deposited was 0·0446 gramme.

The results obtained by the double oxalate method and by precipitation in acetic acid solution were unsatisfactory, but good results were obtained from a formate solution when certain conditions were rigidly maintained. Not more than 0·1 gramme of cadmium in 150 c.c. of solution could be determined on a surface not less than 100 square cm. The voltage might not exceed 3·4 and the ampèrage 0·15-0·20.

The following is given as a representative determination: To a solution of cadmium sulphate 6 c.c. of formic acid (specific gravity 1·20) were added, followed by potassium carbonate until there was a slight permanent precipitate. This was just dissolved in formic acid, and then 1 c.c. excess of the latter added. The solution was diluted to 150 c.c., put in a weighed platinum dish, and placed in the thermopile current for twelve hours. Highest voltage, 3·3; ampèrage, 0·195.

Weight of Cadmium taken.	Weight of Cadmium found.
0·0454	0·0452
0·0454	0·0454
0·0642	0·0642
0·0642	0·0642
0·0642	0·0641



The plates deposited showed no tendency to oxidize, and could be kept in the desiccator for several days. The determinations made in more concentrated solutions, and with stronger currents, often failed to give a good adherent plate. C., A. M.

Separation of Tellurium and Antimony. W. Muthmann and E. Schröder. (*Zeit. anorgan. Chem.*, 1897, xiv., 432.)—As most of the natural compounds of tellurium, including the Hungarian ores Sylvanite and Nagyagite, contain antimony, it is frequently necessary to effect a separation between these two elements; but neither Rose's process—in which the tellurium is precipitated with sulphurous acid—nor Wöhler's—which depends on the formation and subsequent oxidation of potassium telluride—is really trustworthy.

The authors find that tellurium sulphide is an extremely unstable body, and that the metal which results from its decomposition is insoluble in hydrochloric acid not exceeding 20 per cent. in strength; and on these facts they have based the following process. Tartaric acid is added to the hydrochloric acid containing the two oxides Sb_2O_3 and TeO_2 in solution, and a current of sulphuretted hydrogen is passed through it for several hours. The precipitate is warmed and digested with a small excess of potassium sulphide till all is dissolved; and the liquid is then poured into hot 20 per cent. HCl, also containing some tartaric acid, and allowed to rest until the precipitate has settled. The latter is filtered off, washed twice on the filter with hot hydrochloric acid, and afterwards with a weak solution of tartaric acid till it is free from antimony. In order to determine the tellurium, the precipitates must be dissolved in fuming nitric acid, and the metal either weighed as such or as dioxide.

Some examples of the process as applied to known mixtures are given in the paper, with results showing an average deficit of 0·43 per cent. in the case of the tellurium, and of only 0·21 per cent. in that of the antimony; and the authors have also analysed an almost perfectly clean specimen of nagyagite (tellurium glance) from Nagyag, finding its composition to be accurately represented by the empirical formula $Pb_{10}Au_2Sb_2Te_6S_{15}$, which may perhaps be expressed more rationally as $Sb_2Te_3.Au_2Te_3.5Pb_2S_3$. F. H. L.

Quantitative Separation of Arsenic and Antimony. **Oscar Piloty and Alfred Stock.** (*Berichte*, 1897, p. 1649.)—The method is based on the fact that arsenic, when present in a strong hydrochloric acid solution, is readily volatilized by hydrogen sulphide. This fact may also serve to explain the many contradictions found in literature with reference to the precipitation of arsenic as sulphide. If strong hydrochloric acid, containing arsenic trisulphide, is kept in a state of ebullition the arsenic for the most part volatilizes; and in such a solution of either arsenic trioxide or pentoxide no precipitation of sulphide occurs on passing hydrogen sulphide through it; but if the solution is kept boiling, and a current of hydrochloric acid gas is simultaneously passed into it, the arsenic passes over probably as trichloride. From the above it is easily seen that complete precipitation of arsenic by hydrogen sulphide can only take place in a hot solution when this is slightly acid, or in a cold solution when it is strongly acid (*cf.* Bunsen, *Ann. d. Chemie*, 1892, p. 305). In the method proposed the mixture of arsenic and antimony is introduced into a 300 c.c. round-bottomed flask, along with 100 c.c. of strong hydrochloric acid. This flask A is closed with a cork having two perforations, and bearing the arrangement of tubes shown in the accompanying figure, the upper tube serving for the introduction of a current of hydrochloric acid gas, the lower for a current of hydrogen sulphide. A wide-mouthed Erlenmeyer flask E of 600 c.c. capacity, placed in ice, and containing 250 c.c. of dilute hydrochloric acid, serves as the receiver. This flask is covered with a perforated watch-glass, through which the tube D passes and dips under the surface of the liquid. The contents of flask A are brought to a state of lively ebullition, and a rapid current of hydrochloric acid gas is passed through its contents. As soon as the flask has attained the temperature of boiling water, hydrogen sulphide is admitted at the rate of two small bubbles per second. The distillation is rapidly pushed on until only a few c.c. are left in the flask; this occupies from half to three-quarters of an hour. It is best to shut off the current of hydrogen sulphide a short time before the distillation is finished, so that the distilling-flask may be freed from this gas. The whole of the arsenic, which is now present in the receiver as sulphide, is brought on to a filter-paper supported on a perforated filter-plate, dissolved, as also are the portions adhering to the sides of the receiver, in potassium hydroxide solution, and made up to 500 c.c. It is then oxidized with bromine-water, after being slightly acidified with hydrochloric acid, boiled to remove bromine, kept at a temperature of 70° C. for three hours, with a current of hydrogen sulphide passing,

this being maintained until the liquid is cold. After standing for twelve hours, the granular precipitate of arsenic pentasulphide is collected in a Gooch crucible, washed with water, absolute alcohol, carbon disulphide, water-free ether, and dried to constant weight at 105° C.

The contents of flask A, which contains the antimony, are precipitated with hydrogen sulphide, and the precipitate treated in a similar manner to that from the arsenic.

The results obtained are exact. W. J. S.

Qualitative Separations of the Bases of the Second Group in the Absence of Phosphates, etc., by Sodium Nitrite. G. Wynkoop. (*Jour. Amer. Chem. Soc.*, 1897, xix., 434-436.)—Iron, aluminium, and chromium are completely precipitated by sodium nitrite if the solution is boiled for a short time, whilst cobalt, nickel, zinc and manganese are unaffected if a small amount of acid be present in the solution. When iron and chromium are precipitated in the presence of zinc, not more than inappreciable quantities of the latter are simultaneously carried down. The separation of iron from manganese was found to be more accurate and rapid than with barium carbonate. In the cold, iron and some of the cobalt (the latter as double nitrite of cobalt and sodium) are precipitated, while chromium and aluminium do not come down until the solution is heated nearly to the boiling-point. Iron is best precipitated in the ferrous state, since the precipitate is less bulky and gelatinous than the ferric iron, and consequently more easily washed. C. A. M.

A Modification of the Permanganate Method for the Determination of Iron. H. P. Cady and A. P. Ruediger. (*Jour. Amer. Chem. Soc.*, 1897, xix., 575-581.)—Since silver nitrate gives no precipitate in a dilute solution of a chloride in the presence of an excess of mercuric sulphate, and also since silver chloride is moderately soluble in a solution of mercuric sulphate, the authors made experiments to determine whether iron could not be titrated with permanganate in the presence of hydrochloric acid if an excess of mercuric sulphate were added to the solution. The results were very satisfactory, and two methods were worked out:

Method I.—The substance is dissolved in water containing hydrochloric acid, diluted to 100 c.c., boiled and reduced with stannous chloride solution (5 per cent.) added little by little until the solution becomes colorless. Any excess of stannous chloride is oxidized by adding a solution of permanganate drop by drop until a drop of the iron solution gives a faint colour with potassium thiocyanate. One or two drops (not more) of stannous chloride are then added. This whole process should be carried out at boiling heat. The solution is then cooled, 50 c.c. of dilute sulphuric acid added, followed by 35 c.c. of mercuric sulphate solution for every 10 c.c. of hydrochloric acid that was used. This solution is prepared by adding to 200 grammes of mercuric sulphate 80 c.c. of sulphuric acid (conc.), and adding to the paste 800 c.c. of water. To this is added 100 grammes of ortho-phosphoric acid dissolved in a little water, and the whole is diluted to 1 litre. After the addition of the mercuric sulphate,

the solution is diluted to 400 c.c., and titrated with potassium permanganate as usual.

Method II.—The substance is dissolved in 15 c.c. of hydrochloric acid (specific gravity 1·10), 2 c.c. of the mercuric sulphate solution added, the whole heated to boiling, and stannous chloride added in small quantities at a time, until the addition of a single drop produces a turbidity which does not redissolve on boiling. The contents of the flask are rinsed into a beaker, diluted to about 300 c.c., 50 c.c. of dilute sulphuric acid added, and then 45 c.c. of the mercuric sulphate solution; the solution may then be titrated without further cooling.

Method I. can be used in all cases, while Method II. (which is much shorter) can be used when there is not too much insoluble residue which might obscure the reaction at the end of the reduction. The test analyses of ammonium ferric sulphate gave results closely corresponding with those required by theory, but those obtained by Method II. were about 0·1 per cent. too high.

Application of the Process to Iron Ores.—The material is boiled for some time with 10 to 15 c.c. of hydrochloric acid (specific gravity 1·10), with the addition of stannous chloride solution to hasten the decomposition. If Method I. is to be followed, the solution is diluted to 100 c.c. and treated as described. When Method II. is followed, the solution is not diluted, but the 2 c.c. of mercuric sulphate are added, and the process continued as before. If long boiling was required to dissolve the ore, much of the acid may have been driven off, and the precipitate formed on the addition of stannous chloride will not readily redissolve; in such cases a few more c.c. of hydrochloric acid should be added. Ores insoluble in hydrochloric acid may be dissolved after fusion with potassium hydrogen sulphate, and then reduced by either method.

The special precautions to be taken in the process are:

1. The stannous chloride must be in good condition. It should give no precipitate when diluted with twenty volumes of water and boiled.

2. The smallest possible excess of stannous chloride should be present after the reduction is completed.

3. The proportion between the mercuric sulphate and the hydrochloric acid must be carefully adjusted.

It is stated that, in the case of soluble salts, less than three minutes has been found sufficient time for solution, reduction, and titration. C. A. M.

The Employment of Copper Salts in the Estimation of Certain Elements in Cast Iron and Steel. A. Carnot and E. Goutal. (*Ann. de Chim. Analyt.*, ii. [16], 301-305.)

1. *Carbon.*—The rapidity of the ordinary method of attacking the metal by a solution of a cupric salt may be increased by the following modification: From 2 to 5 grammes of the sample, either in lumps or cuttings, are placed in a conical 300 c.c. flask, with a base 12 cm. in diameter, and containing a perforated disc (11 cm.) of platinum to induce electrical action. For each gramme of metal 50 c.c. of a 30 per cent. solution of cupric potassic chloride are taken, 4 or 5 drops of hydrochloric acid

added, and, after boiling for a few seconds, cooled down to 60° C. The metal is then introduced, and the temperature raised to 90°-95° C. To keep the liquid agitated, and at the same time to prevent oxidation of the iron, a current of carbon di-oxide is passed through it continuously. Under these conditions the attack is rapid, fine clippings being dissolved in about twenty minutes, and 5 gramme lumps in an hour and a half. When the precipitated copper is dissolved, the residual carbon is brought by means of the solvent on to an asbestos filter, washed first with acid cupric chloride solution, then with hot water, and burned without previous desiccation. The results are concordant with those furnished by the longer method.

2. *Sulphur.*—The same procedure is adopted, but the washed precipitate is treated with a mixture of 5 c.c. of hydrochloric acid, 15 c.c. of water, and 1 c.c. of bromine in the cold, the temperature being after some time raised slowly to boiling to expel the bromine. After neutralizing the filtered liquid with ammonia and adding a few drops of hydrochloric acid, the sulphur is precipitated as barium sulphate, and either weighed direct, or first purified from slight traces of silica by the addition of hydrofluoric acid and evaporation with a few drops of sulphuric acid.

3. *Phosphorus.*—The metal is attacked by a *neutral* solution of cupric-potassic chloride in the same apparatus, and the residue, after washing, is treated with nitric acid and bromine; then filtered and boiled with a few decigrammes of chromic acid to destroy the carbides. After neutralizing with ammonia, a few drops of nitric acid are added, followed by 50 c.c. of nitro-molybdic reagent at about 45° C., to precipitate the phosphoric acid. Experience has shown that when the temperature is very moderate, and the amount of iron present very small, the precipitate is normal, and may be washed, dried at 100° C., and weighed direct. The silica is eliminated, and there is no necessity for evaporation to dryness; and any arsenic present is dissolved by the copper salt.

4. *Chromium.*—When the solvent is perfectly neutral the chromium is left undissolved, and may then be determined from the washed and calcined residue by acting on the latter with sodium peroxide, taking up with water, boiling and estimating the chromic acid. The method, though advantageous in the case of steel with a low content of chromium, is less so when the metal is poor in carbon, the chromium in such cases being partly dissolved by the copper salt.

5. *Tungsten and Titanium.*—These are also left undissolved in the residue, in the condition of oxides when in small quantity, but partly in the metallic state when present in larger amounts.

The calcined residue, freed from silica by hydrofluoric acid, is attacked by a mixture of potassium nitrate and carbonate (8 : 2), and taken up with water. The tungstic acid is thereby completely dissolved, and is then thrown down as mercurous tungstate, which is washed, calcined in an oxidizing flame, and finally weighed as pure tungstic acid. The titanic acid remains in the residue, and is determined by fusing with potassium bisulphate, reducing the aqueous solution by sulphur dioxide, and precipitating by boiling with sodium acetate.

When the precipitates are very small, their constituents may be distinguished (after fusion with $KHSO_4$, heating with a few drops of sulphuric acid, and cooling) by their colour reaction with hydroquinone, titanic acid giving a crimson-red and

tungstic acid an amethyst-violet. This reaction enables traces of tungstic acid (too small to be found by any other method) to be detected in the original residue, if it be first treated with concentrated ammonia, evaporated, and the hydroquinone test as given above applied. C. S.

The Impurities of Commercial Calcium Carbide. H. Le Chatelier. (*Bull. Soc. Chim.*, 1897, 793, 794.)—After calcium and carbon, the two most abundant elements in commercial calcium carbide are silicon and iron. The latter is present in the smallest proportion, and is exclusively combined with the silicon. On mixing the carbide with water and treating the insoluble residue with methylene iodide, small crystals of iron silicide, $SiFe_2$, settle out.

The excess of silicon above that required by the iron may be in combination with either the calcium or the carbon. If there is an excess of carbon over calcium, silicide of carbon will be found, crystallized in hexagonal plates, and usually of a blue colour. It will be seen floating on the surface of the methylene iodide, together with the excess of graphite.

If, on the other hand, there is an excess of calcium over carbon, calcium silicide will be found disseminated throughout the mass of the carbide in metallic grains having the colour and appearance of zinc. These can be isolated by treating the carbide rapidly with a large excess of cold water, separating the heavier residue by lixiviation and washing it for several seconds with dilute acetic acid. The final residue consists of iron silicide, and the larger grains of calcium silicide. In this case there can be neither graphite nor silicide of carbon, since there must be an excess of calcium for the formation of calcium silicide.

Apparently there are two distinct silicides of calcium One is not easily attacked by nitric acid, but is readily decomposed by hydrochloric acid, with the formation of a yellow insoluble body—the silicone of Wöhler. The other is readily attacked by nitric and acetic acids, and gives with hydrochloric acid a white compound, which, like silicone, dissolves in potash, with an abundant liberation of hydrogen. The yellow and white compounds have compositions corresponding to the formulæ $Si_2O_4H_4$ and $Si_2O_3H_4$ respectively. C. A. M.

Determination of Lime in Calcined Magnesite. R. Hefelmann. (*Zeit. für öffent. Chemie*, iii., 193.)—Whilst the separation of a small amount of magnesia from a large amount of lime presents no particular difficulty, the reverse operation is not so simple a matter. The following process is recommended as giving satisfactory results, the separation being complete without the need of having to resort to a second precipitation:

1 gramme of magnesite is taken and the silica separated in the usual way. The iron is then removed by double precipitation, the filtrate slightly acidified with hydrochloric acid, and the solution made up to 500 c.c. To 250 c.c. of the solution are added 3 grammes of pure ammonium chloride and ammonia to alkaline reaction. 250 c.c. of water are then added, and the lime precipitated in the solution, while boiling, by 2 grammes of ammonium oxalate dissolved in 100 c.c. of water. When

precipitated in this way, the lime is found to be quite free from both magnesium hydrate and magnesium ammonium oxalate. H. H. B. S.

The Determination of Thorium in Thorite. E. Hintz and W. Weber. (*Zeit. anal. Chem*, 1897, xxxvi., 27-31.)—This method is based on the facts that thorium can be precipitated from slightly acid solution by means of oxalic acid, that thorium oxalate is soluble in ammonium oxalate, and that it can be precipitated from such solution by means of hydrochloric acid or ammonia.

One gramme of the mineral is decomposed with concentrated hydrochloric acid and the liquid evaporated to dryness to separate silica. The residue is moistened with 2 c.c. of concentrated hydrochloric acid and the silica filtered off and washed. Copper or lead, if present, are then removed by precipitation with sulphuretted hydrogen, the filtrate boiled to completely expel the excess of reagent, and made up to 200 c.c. A solution of oxalic acid (containing 1 gramme) is added to the hot solution, and after standing for two days the precipitate is filtered off, washed, and digested for several hours on a boiling water-bath with 60 c.c. of a cold saturated solution of ammonium oxalate. The liquid is diluted to 300 c.c., allowed to stand for two days, then filtered, and the filter washed with water containing a trace of ammonium oxalate. The filtrate is heated and 5 c.c. of concentrated hydrochloric acid (specific gravity 1·17) added.

Any residue remaining after the treatment with ammonium oxalate is again digested with 20 c.c. of the ammonium oxalate solution, the liquid made up to 100 c.c. and 1·7 c.c. of concentrated hydrochloric acid added. Should there be a precipitate, the treatment with ammonium oxalate is repeated a third time, and, if necessary, a fourth time.

The precipitates of thorium oxalate formed by the addition of hydrochloric acid are left for two days, then collected on a filter, washed with water containing a little hydrochloric acid, ignited and weighed.

The thoria, as thus obtained, always contains a certain amount of foreign earths, since the oxalates of cerium and yttrium are not completely insoluble in ammonium oxalate. The weighed precipitate is therefore dissolved by boiling with strong hydrochloric acid; or if the thoria cannot in this way be completely dissolved, it is fused with acid potassium sulphate, the melt dissolved in water containing hydrochloric acid, ammonia added, and the precipitate filtered off, washed, and dissolved in hydrochloric acid.

The hydrochloric acid solution is evaporated to dryness, the residue dissolved in water containing 2 or 3 drops of dilute hydrochloric acid, and the solution (about 300 c.c.) boiled for several minutes with 3 or 4 grammes of sodium thiosulphate. When cold, the precipitate is filtered off and washed. Ammonia is added to the filtrate, and the resulting precipitate separated and dissolved in hydrochloric acid. The solution is evaporated to dryness, the residue taken up in a little water, and the liquid boiled with a hot concentrated solution of ammonium oxalate. After being left for some time in the cold, the precipitate (oxalates of cerium and yttrium) is filtered off, washed, ignited, and weighed. This last weight deducted from the weight of the crude thoria gives the amount of pure thoria.

In exceptional cases of very impure thorite the residue from the ammonium oxalate must be dissolved in hydrochloric acid, or, if necessary, fused with acid potassium sulphate, and the hydrochloric acid solution obtained as described above. This solution is evaporated to dryness, the residue taken up in a few drops of hydrochloric acid, the solution diluted to about 100 c.c., and boiled with sodium thiosulphate. The precipitate is dissolved in hydrochloric acid, the solution evaporated to dryness, the residue taken up in very dilute hydrochloric acid, the thorium precipitated with oxalic acid, and the precipitate united to and weighed with the main precipitate.

Since the precipitation of thorium with sodium thiosulphate is sometimes incomplete, ammonia should be added to the filtrate. The resulting precipitate, consisting of cerium oxides and yttria, with trifling quantities of thoria, is dissolved in hydrochloric acid, the solution evaporated to dryness, the residue taken up in water, the solution boiled, and a hot concentrated solution of ammonium oxalate added. The solution is diluted, allowed to stand for twenty-four hours, the thorium precipitated with ammonia, and the precipitate separated, washed, ignited, and weighed with the main precipitate. C. A. M.

Volumetric Estimation of Iodides with Iodic and Arsenious Acids. F. A. Gooch and C. F. Walker. (*Zeit. anorgan. Chem.*, 1897, xiv., 423.)—This process somewhat resembles Riegler's (ANALYST, xxii., 25), in that the iodide is decomposed by iodic acid; but after the liquid has been made alkaline, the whole of the liberated iodine—five-sixths of which is derived from the iodide itself—is titrated by means of arsenious acid. In order to avoid loss of halogen, the operation is conducted in a modified form of Drexel's wash-bottle, in which the inlet tube carries a funnel and a stopcock, while the outlet is fused to a set of Will and Varrentrapp's nitrogen bulbs. The liquid containing from 0·08 to 0·4 gramme of the iodide to be analysed is measured into the bottle, 5 c.c. of a 5 per cent. solution of potassium iodate added, and the mixture diluted to 150 c.c. The stopper is then inserted in its place, and the bulbs are half filled with 5 per cent. potassium iodide. 5 c.c. of 1 : 3 sulphuric acid are run in through the funnel, the cork closed, and the vessel gently shaken. An excess (10 c.c.) of a saturated solution of potassium bicarbonate is next introduced gradually, the cock closed once more, and, without allowing any of the liquid in the bulbs to run back before neutrality is reached, the flask is cautiously agitated till all violet vapours have disappeared. Finally the bulbs are emptied into the flask, the stopper is removed, and all its parts are rinsed into the main portion of the liquid. This is titrated with decinormal arsenious acid till it becomes colourless, and the exact end-point of the reaction is determined with iodine and starch.

It is important that the volume of the liquid at the time of acidification be exactly 150 c.c., and that there be no appreciable amount of chlorides or bromides present; but in other respects alterations in the proportions of the different reagents seem of little moment. The process is manifestly best adapted for the valuation of approximately pure potassium iodide; in this case the factor 0·01383 at once converts the c.c.'s of arsenious acid into grammes of KI. F. H. L.

Purification of Hydrochloric Acid. E. Gravier. (*Rev. de Chim. Analyt. Appl.*, v. [17], 329-330.)—By distilling the hydrochloric acid as rapidly as possible until some two-thirds has passed over, the author finds the residual portion to be entirely free from arsenic. C. S.

A Colour Reaction for Di-Sulphuric Acid. E. Barral. (*Bull. Soc. Chim.*, 1897, 744, 745.)—When benzene-hexachloride para-dichloride ($C_6Cl_6.Cl_2$) is added little by little in a state of fine division to sulphuric acid containing the di-sulphuric acid, a brilliant reddish-violet colour is produced. On the addition of water or sulphuric acid, or even on exposure to moist air, the colour disappears as the acid becomes transformed into ordinary sulphuric acid. That the coloration is not due to impurities in the Nordhausen acid is proved by the fact that pure SO_3, prepared by passing $SO_2 + O$ over spongy platinum, gives the reaction on exposure to moist air.

This disappearance of the red colour as ordinary sulphuric acid is formed, is used by the author as the basis of a volumetric method for determining di-sulphuric acid. A little powdered C_6Cl_8 is added to the Nordhausen acid, which is shaken until the colour appears.

Standard sulphuric acid (acid of 66° with about one-tenth of its weight of water) is then added drop by drop until the colour disappears, and from the amount required the quantity of di-sulphuric acid in the Nordhausen acid is readily calculated.

This method of direct titration gives good results when the acid is colorless, or nearly so, but with many of the Nordhausen acids of commerce it is not so sensitive.

C. A. M.

Reactions of Sulphoxyarsenic Acids. L. W. McCay. (*Chem. Zeit.*, 1897, xxi., 487.)—If a moderately dilute solution of sodium orthomonosulphoxyarseniate is treated with strontium chloride, a white amorphous precipitate consisting of $NaSr_2(AsO_3S)_2,17Aq$ immediately falls, which becomes crystalline on shaking. Similarly, on adding barium chloride to the disulphoxy salt of sodium, a glittering white precipitate of $Ba_3(AsO_2S_2)_2,7Aq$ is rapidly produced. In mixtures of the two acids the di- salt may be tested for with barium after removal of the mono- acid by agitating with strontium chloride for five minutes as above. Since the sulpharsenites and sulpharseniates of the alkaline earths are all soluble in water, these reactions are not impeded by the presence of large quantities of the former. Calcium chloride behaves analogously to the strontium compound, therefore sodium orthodisulphoxyarseniate may be employed to separate barium from strontium or calcium.

F. H. L.

Estimation of Nitrous Acid and Nitrites. B. Grützner. (*Arch. Pharm.*, 1897, ccxxxv., 241; through *Chem. Zeit. Rep.*, 1897, 172.)—This process depends on the reaction $3HNO_2 + HClO_3 = 3HNO_3 + HCl$. 0·1 or 0·2 gramme of the nitrite is dissolved in 500 cc. of water, treated with about 0·5 gramme of potassium chlorate free from chloride and a definite amount of decinormal silver nitrate, strongly

acidified with nitric acid, well shaken up for some minutes, and the excess of silver titrated with sodium chloride. One c.c. of decinormal silver is equivalent to 0·0142 gramme of HNO_2 or 0·0114 gramme of N_2O_3.

Similarly the N_2O_4 in fuming nitric acid may be determined by diluting 5 c.c. of the sample with 750 c.c. of water, and proceeding as above. Three molecules of N_2O_4 correspond to 1 molecule of $AgNO_3$, or 1 c.c. of decinormal silver equals 0·0276 gramme of nitrogen tetroxide. F. H. L.

An Extremely Sensitive Reaction for Nitrites, and its Quantitative Application. E. Riegler. (*Zeit. anal. Chem.*, 1897, xxxvi., 377, 378.)—In a former communication (*Zeit. anal. Chem.*, xxxv., 677) the author recommended naphthionic acid as a sensitive reagent for nitrous acid. In place of this he now describes a reagent twenty times more sensitive. This is prepared by shaking 2 grammes of chemically pure sodium naphthionate and 1 gramme of β-naphthol (purissim.) with 200 c.c. of water, and filtering. The solution is colorless, and can be preserved in the dark without alteration.

The test is applied by adding to 10 c.c. of the liquid to be examined 10 drops of the reagent and 2 drops of concentrated sulphuric acid, and shaking the mixture several times. On now adding about 20 drops of ammonia, a rose-coloured ring is formed at the junction of the liquids, and on shaking the tube the whole liquid becomes red or rose-coloured, according to the amount of nitrous acid present. The reaction depends on the conversion of the naphthionic acid by means of the nitrous acid into diazo-naphthalin-sulphonic acid, which forms with β-naphthol and ammonia a red diazo colouring matter. One part of nitrous acid in a million can be detected in this way.

In using the reaction for the quantitative determination of nitrites, a standard solution is prepared by dissolving 0·406 gramme of pure dry silver nitrite in hot water, adding sodium chloride, and, after cooling, diluting to a litre. When the precipitate has settled, 10 c.c. of the clear solution are removed with a pipette, and made up to a litre. 100 c.c. of this solution (containing 0·0001 gramme of N_2O_3) are placed in a flask, 20 to 30 drops of the naphthol reagent and 4 drops of concentrated sulphuric acid added, the mixture well shaken, about 20 drops of concentrated ammonia solution added, and the liquid again well shaken. The colour of the resulting liquid is compared by means of a colorimeter with that given under the same conditions by 100 c.c. of the liquid to be examined. If the latter contain more than 0·0001 gramme of N_2O_3 in 100 c.c., it must be previously diluted with distilled water. The standard solution must be freshly prepared before each determination. In this way it is possible to estimate 0·00005 gramme of N_2O_3 in a litre of water.

The naphthol reagent may also be used in the dry state. Equal parts of naphthionic acid and β-naphthol are intimately mixed in a mortar, and a pinch of the powder used instead of the 20 drops of the solution. The powder has the advantage of keeping absolutely without alteration, whilst the reaction given by it is equally delicate. C. A. M.

Preservation of Solutions of Oxalic Acid. **E. Fricke.** (*Chem. Zeit.*, xxi., 26, 243.)—This paper deals with the instability of $\frac{N}{100}$ oxalic acid, which, it is said, can be prevented by the addition of boric acid to the solution.

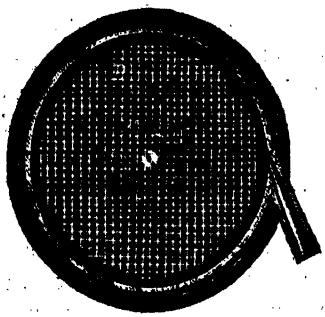
Note on the Analysis of the Sodium Sulphide used in Leather-dressing. **F. Jean.** (*Ann. de Chim. Analyt.*, ii. [18], 341-343.)—A sample of sodium sulphide that had produced spots (recognised as due to iron) on doe-skin during the cleansing and plumping processes was found to form a green aqueous solution, depositing a sediment of iron sulphide, whilst a second sample containing an equal amount of iron gave a yellow solution, without yielding a deposit of sulphide or spotting the skins. For determining the sodium thiosulphate and the excess of sulphur in these samples, the following method was elaborated. Ten grammes of an average sample of the crystallized substance are dissolved in water, the iron sulphide deposit being determined in the insoluble portion. The filtrate is made up to 1 litre, and 10 c.c. of this are titrated with $\frac{N}{10}$ iodine and starch paste to determine the *total sulphur* present. A second 10 c.c. are mixed with 30 c.c. of water and a quantity of ammonium sulphate solution (6·7 grammes $(NH_4)_2SO_4$ per litre) equal to the volume of iodine used in the first test, and distilled, the retort being connected with the upper end of a vertical condenser, the lower end of which dips into 2 c.c. of $\frac{N}{10}$ acid. The operation is suspended when the distillate coming over ceases to have an alkaline reaction. After boiling, to expel hydrogen sulphide, the excess of acid in the receiver is titrated with $\frac{N}{10}$ alkali and litmus, 1 c.c. of the acid saturated by the distilled ammonia corresponding to 0·0039 gramme of *sodium sulphide*. The residual liquid in the still is cooled and titrated with $\frac{N}{10}$ – iodine, 1 c.c of which reagent = 0·0079 of *sodium thiosulphate*. The difference between this and the former iodine titration is calculated as sodium sulphide. By deducting from this the amount determined in the acid titration, a difference is obtained which represents in terms of Na_2S the excess of sulphur present as *polysulphide*, and may be calculated to sulphur (100 Na_2S = 41S). When the monosulphide is pure, the results of the iodine and ammonia tests will be identical.

The composition of the two samples examined was:

	Green Sulphide.	Yellow Sulphide.
Water	63·24	60·32
Sodium sulphide	31·20	28·08
Sulphur in excess	0·53	1·20
Sodium thiosulphate	4·70	10·00
Iron sulphide	0·33	0·40



Two hitherto unrecorded observations were made in the course of the investigation, viz., (1) That when a solution of an alkaline monosulphide is boiled with an excess of ammonia, part of the sulphur is volatilized as ammonium sulphide. (2) In *boiling* sodium thiosulphate with excess of ammonium sulphate, ammonium sulphide is liberated and sulphur deposited. This decomposition, however, does not occur in an alkaline medium.

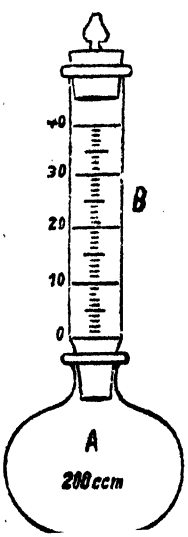
APPARATUS.

A New Laboratory Turbine. H. Tryller. (*Berichte*, 1897, p. 1729.)—In this motion is produced by the friction of a jet of water which impinges on a disc of wire gauze, in contradistinction to the usual form where the rotation is caused by the impulse of the jet against a series of floats attached to a wheel. The new form works much more evenly and noiselessly than the older forms, and the rate of motion, as governed by the supply of water, is under better control. The accompanying illustration shows the general form of the apparatus:



A is the cylindrical case, 100 mm. in diameter and 5 mm. high. The interior is almost completely filled by the disc B, which consists of a double layer of the ordinary iron wire gauze used in the laboratory. This is mounted on an axle, to which the pulley C is attached. The jet of water is directed tangentially towards the periphery of the disc, and is discharged at its centre into the tube D. The apparatus is manufactured by Kähler and Martini, Berlin. W. J. S.

Apparatus for Rapidly Estimating Fatty Acids and the Hehner Number. G. Possetto. (*Boll. Chim. farmac.*, 1897, p. 225; through *Chem. Zeit. Rep.*, 1897, p. 197.)—This consists of a flask of 200 c.c. capacity, with a stoppered tube ground in, as seen in the figure, graduated into forty divisions. The dissolved soap having been decomposed by dilute sulphuric acid in the flask, the tube is fixed in position, the liquid made up to the zero mark on the scale, and ether poured in to the thirty-fifth division. After well shaking and being allowed to settle, an aliquot part of the ethereal solution is removed, evaporated to dryness, and the fatty acids weighed. For ascertaining the Hehner number, the butter or other fat is first saponified in an alcoholic potash solution.

REVIEWS.

ATLAS AND ESSENTIALS OF BACTERIOLOGY. By K. B. LEHMANN and RUDOLF NEUMANN. (London, Baillière, Tindall and Cox.) Price 12s. 6d.

The first portion of this admirable work consists of a series of sixty-three plates, beautifully executed in colours, which give the appearances exhibited by superficial and deep-seated colonies when grown on gelatin and agar media, as well as in potato cultures; also illustrations of the general appearances in streak and stab cultures, a separate representation being given of the puncture canal and of the surface of the punctured medium in the latter form of culture. These are in many cases supplemented by woodcuts of the organisms. The second portion of the book contains a description of the morphology, vital conditions, sporulation, etc., of bacteria, followed by an account of the effects produced by them, either through the enzymes which they secrete, or simply by metabolism; of the production of pigments, toxins, etc. The technical appendix, which concludes the work, contains a number of useful hints for the bacteriologist when engaged in the actual work of cultivation, but it is evidently assumed that the reader already possesses some rudimentary knowledge of the methods of bacteriological research. These hints are all the more valuable because they bear the impress of being the outcome of long practical experience. The language employed, though occasionally somewhat idiomatic, is intelligible. The work cannot fail to be a valuable addition to the library of the bacteriologist.

W. J. S.

BACTERIOLOGICAL DIAGNOSIS. By ST. GEORGE REID. (London, Baillière, Tindall and Cox.) Price 3s. net.

This is an analytical key for the identification of all the known bacterial micro-organisms, arranged, to use a rough simile, much on the same lines as the tables found in works on qualitative analysis for the identification of the various bases and acids. The tests employed for differentiating the various bacteria are their forms—rods, cocci, etc.—the form of the colonies, their action on the gelatin medium, colour of the colonies, etc. The author is to be commended on the ingenuity displayed in the general arrangement of the key, which seems well adapted for fulfilling its intended purpose. The work will be found useful by those engaged in bacteriological work.

W. J. S.

THE ANALYST.

DECEMBER, 1897.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, November 3, in the Chemical Society's Rooms, Burlington House, the President, Dr. Bernard Dyer, occupying the chair.

The minutes of the previous meeting were read and confirmed.

The following gentlemen were proposed for election as members: Mr. S. H. Collins, F.I.C., Dehra Dun, N.W.P., India, Assistant Agricultural Chemist to the Indian Government; Professor James Hendrick, B.Sc., F.I.C., the University, Aberdeen, District Agricultural Analyst for the County of Aberdeen; Mr. W. H. Jackson, Analyst to the West Yorkshire Coal and Iron Company; and Mr. E. H. Roberts, Analyst to the Dairy Supply Company, Ltd.

Dr. W. J. Russell, F.R.S., was unanimously elected as honorary member of the Society.

The following papers were read:

"The Estimation of Acetates in the Presence of Inorganic Salts." By Bertram Blount.

"The Estimation of Carbonic Acid in Natural Waters." By C. A. Seyler, B.Sc.

"The Detection of Gelatin in Cream;" "A New 'Milk-Preservative';" "A New Milk-Adulterant." By A. W. Stokes.

"Note on the Graduation of Leffmann-Beam Bottles." By G. E. Scott-Smith and A. B. Searle.

"An Improved Milk Scale."

THE DETERMINATION OF ACETIC ACID IN THE PRESENCE OF INORGANIC SALTS.

BY BERTRAM BLOUNT, F.I.C.

(*Read at the Meeting, Nov.* 3, 1897.)

A SHORT time ago I had occasion to determine the quantity of acetic acid present as an acetate in a mixture composed essentially of magnesia, magnesium chloride, and lead acetate, the amount of the last-named ingredient being relatively small. The question appears simple, but, as a matter of fact, required some little consideration and experiment before a satisfactory method was devised.

It may be observed that, acetic acid being a comparatively strong organic acid,

no method such as is commonly used to estimate weak organic acids in the presence of mineral acids (*e.g.*, by titration with selective indicators) was available. The most obvious way, therefore, was to eliminate the chloride as silver chloride, and determine the acetic acid in the filtrate in any convenient manner.

But it was by no means certain that if the mass, which as a whole is sparingly soluble, were extracted with water, it would yield all its acetate. The natural solvent, nitric acid, was not to be thought of, as the separation of this acid from acetic acid is not easy. Hydrochloric acid would require the use of an inconveniently large quantity of silver salt for precipitation. Treatment of the original substance with caustic soda or sodium carbonate, and obtaining all acids as sodium salts, presented some attractions; but, on consideration, it appeared that the bulky mass of magnesia, magnesium hydroxide, and lead hydroxide, which would be left, would be apt to retain soluble salts, including the acetate sought for.

Accordingly, the mixture was dissolved in the cold in sulphuric acid, the chloride precipitated with silver sulphate, and the filtrate distilled into baryta water. The excess of baryta was precipitated by CO_2, and the solution containing the barium acetate evaporated to dryness and the residue weighed. The percentage found fell far short of the truth. It appeared that silver acetate, which is a sparingly soluble salt, could not be separated from the large quantity of silver chloride, unless enormous quantities of washing water were used, making the subsequent distillation tedious and troublesome. Separation by means of silver was, therefore, abandoned.

The plan ultimately adopted was simple and completely satisfactory. It depends on the solubility of sodium acetate in alcohol. The mixture containing magnesia, magnesium chloride, lead acetate, and the products of their interaction, was distilled with excess of sulphuric acid, the distillation being pushed to a point at which the sulphuric acid began to fume. This is necessary in order to ensure driving over the whole of the acetic acid. The distillate was received in a small excess of caustic soda. At the end of the operation the receiver contained sodium chloride, sodium acetate, possibly some sodium sulphate and excess of caustic soda. It was evaporated to a small bulk (but not to dryness), absolute alcohol was added, the whole well stirred, filtered, and washed with absolute alcohol. The alcoholic solution contained sodium acetate and caustic soda. Of these, the latter was eliminated by treatment with CO_2, and on evaporating the filtrate sodium acetate was obtained. The latter still retained a small amount of impurity, and was therefore distilled from a very small retort with excess of sulphuric acid into baryta water, the barium acetate being ultimately separated and weighed.

The method tried on known mixtures proved to be accurate. It appears to be generally applicable, save in the presence of nitric acid. In this case it would probably be best to reduce the nitric acid to ammonia and proceed in the manner already indicated, but I have not had occasion to test the practicability of this plan.

Discussion.

Mr. Allen thought that Mr. Blount had rendered a great service by bringing forward the results of his experience in this matter, and by his sagacity in solving a practical difficulty. It was, unfortunately, not uncommon for the text-books to assume

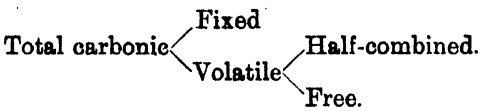
that questions of this kind were very easy to deal with, whereas they often presented very curious difficulties in practice. While hearing the middle stages of the paper, he had felt rather curious as to how far it would fall into conformity with the lines which he, up to a certain point, would have himself adopted. He did not think the use of alcohol would have occurred to him as necessary. He would have thought it quite possible to acidulate the original material with sulphuric acid, and add sulphate of silver, which would give a precipitate of chloride of silver and sulphate of lead, together with a liquid which could be filtered from the precipitate. There would probably be some mechanical difficulty in the manipulation, but apart from this he would have thought that the acetic acid could be distilled over satisfactorily. He had lately been trying how far certain processes were applicable quantitatively for the separation of some of the commoner metals from the ashes of organic matters, like vegetables, meat, etc. (for instance, for the estimation of tin in tinned meat, zinc in cheese, and so forth). His object was to devise a comparatively simple means of determining, in the same portion of ash, zinc, copper, tin and lead, or any one of the four, and it was astonishing how difficult the problem ultimately proved to be. It would seem at first sight a very simple matter to estimate the lead in a mixture of sodium phosphate, calcium phosphate, lead sulphate and sodium chloride, but, as a matter of fact, a simple process for the estimation of lead and tin in the presence of sulphates, chlorides and phosphates was a thing that required a good deal of thinking and working out. As an instance in point, he might mention that Mr. Hehner was accustomed to estimate tin in tinned meat by boiling the ash with hydrochloric acid. He (Mr. Allen) had never been able to obtain the whole of the tin in solution, ignited stannic oxide being practically insoluble in hydrochloric acid.

Mr. HEHNER suggested that a still simpler solution might perhaps be arrived at by proceeding on the principle of a method for the estimation of mineral acids in vinegar, which was contained in a paper read before the Society some years previously by Messrs. Allen and Bodmer, viz., by distilling with sulphuric acid, carefully neutralizing the distillate (which would contain sulphate, chloride and acetate of sodium), igniting and titrating the alkalinity of the ash, which would give the acetic acid present in the distillate. He had never found any difficulty in qualitatively testing the ash of tinned meat. He simply boiled with hydrochloric acid, in which the stannic oxide was not soluble, and then with water, after which it dissolved. On the addition of sulphuretted hydrogen an abundant precipitate of sulphide of tin was often obtained.

Mr. A. C. CHAPMAN said that during the past two or three years he had had considerable experience in the separation of the sodium salts of certain organic acids from inorganic sodium salts by means of alcohol, and he had always found it a very difficult matter to effect a perfect separation. For technical purposes, however, the method would give quite satisfactory results, as was shown by the author of the paper.

The PRESIDENT suggested that the difficulty arising from the presence of nitric acid might possibly be overcome by using barium to catch the nitric acid; barium nitrate would be insoluble in alcohol. The subject of the separation of metals in small quantities under difficult circumstances was one that was constantly coming

forward in analytical laboratories, and it was evident that Mr. Allen had materials for a very interesting paper thereon.



Mr. BLOUNT said that in the particular mixture under consideration the use of barium would lead to the formation of barium chloride, which would be too soluble in alcohol to render the modification practically applicable. He was afraid that in following Mr. Allen's proposition the process of distilling to a small bulk with sulphuric acid would involve the decomposition of the silver chloride.

THE ESTIMATION OF CARBONIC ACID IN NATURAL WATERS.

By CLARENCE A. SEYLER, B.Sc., F.I.C.

(Read at the Meeting, Nov. 3, 1897.)

THE carbonic acid of natural waters may occur in three forms: combined with alkaline earths or alkalies as mono-carbonates, half combined as bicarbonates, and fully-free carbonic acid. Of these the free and half-bound are approximately expelled on boiling, and hence I propose to call them the volatile carbonic acid. This is what is estimated by Pettenkofer's process:

The volatile carbonic acid used to be spoken of as free, but this name must be reserved for that which exists in excess of that necessary to form bicarbonates. The free acid is lost much more readily than the half-bound on exposure to the air.

Pettenkofer's method, though no doubt capable of accurate results with extreme care, is not fitted for the purposes of the busy analyst. It involves the use of many carefully calibrated vessels and frequent standardizing of variable solutions, and even at the best the results are subject to considerable uncertainty. On the assumption that the half-bound acid is equal to the combined, we may estimate the free carbonic acid by subtracting the combined from the volatile, as determined by Pettenkofer's process; but this is inaccurate with small quantities, as well as tedious. We require a rapid and accurate method of estimating the free carbonic acid independently. The proposals of Pettenkofer and Vignon to do so by a direct titration with lime or baryta water, using turmeric or phenolphthalein as an indicator, do not give satisfactory results. Trillich in 1890 appears to have been the first to give a satisfactory process by using sodium hydrate or carbonate, with phenolphthalein as indicator. I have used the process in regular practice since 1892; and in 1894, in the *Chemical News*, vol. lxx., p. 104 *et seq.*, I published the results of a careful examination of the accuracy of the process, together with the results of its application to different classes of water. The method does not seem to have attracted the attention in this country which I believe it deserves, though it is better known in Germany. My object is to direct the attention of analysts to the method, and to supplement my previous

papers with further experience of it. Referring to the journal already cited for details and explanation, I would say that the method depends on the exact neutrality of the bicarbonates, and the alkalinity of the carbonates, whether of the alkalies or alkaline earths, to phenolphthalein. Owing to the difficulty of keeping caustic soda free from carbonic acid, and also on account of its greater delicacy, I use a $\frac{N}{20}$ solution of sodium carbonate. To 100 c.c. of the water a few drops of a neutral alcoholic solution of phenolphthalein are added, and the liquid then titrated (best in a narrow vessel, with continual but not violent stirring) until the occurrence of a faint but permanent pink colour. This gives the free carbonic acid alone.* The combined acid is estimated on the same or a fresh portion of the water by means of methyl orange and $\frac{N}{20}$ acid. The volatile acid is the sum of the two titrations. If the water is neutral to phenolphthalein, it contains only bicarbonates, and no free carbonic acid. If a water is alkaline to the indicator, it can contain no free carbonic acid, and the volatile acid must be less than the fixed. This deficiency can be readily determined by careful titration with $\frac{N}{20}$ hydrochloric acid until the pink just vanishes.

Let m be the number of c.c. of $\frac{N}{20}$ hydrochloric acid required by 100 c.c. of the water, with methyl orange as indicator, p the number of c.c. of $\frac{N}{20}$ sodium carbonate required to produce the pink colour with 100 c.c. of the water, and p' the number of c.c. of acid required to discharge the pink if the water should be alkaline to that indicator. Then—

Free carbonic acid	...	...	1·1 p, or 1·1 $(p - 2m')$ parts per 100,000.
Fixed ,, ,,	...	...	1·1 m parts per 100,000.
Volatile ,, ,,	...	...	1·1 $(m+p)$, or 1·1 $(m-2p')$ parts per 100,000.
Total ,, ,,	...	...	1·1 $(2m+p)$, or 1·1 $(2m-2p')$ parts per 100,000.

Should the water contain free mineral acid, it will be acid to methyl orange, and can contain only free carbonic acid in addition. If m' be the number of c.c. of sodium carbonate required to destroy the pink with methyl orange, p being, as before, the amount necessary to produce the pink with phenolphthalein, then the free carbonic acid is given by the formula:

$$\text{Free } CO_2 = 1{\cdot}1\ (p - 2m').$$

Thus, in any case we can, by two simple titrations on 100 c.c. of the water, completely determine the amount and condition of the contained carbonic acid in a few minutes. The accuracy of the method has been confirmed in the best of possible ways both by myself and Kippenberger by comparison with Pettenkofer's method and gravimetrically.

The presence of ferrous salts in quantity requires a modification of the process, and in the case of highly-mineralized waters, such as the Hunyadi Janos water, some interfering factor remains to be explained; but such cases are rare. I give some examples of Kippenberger's careful comparisons of the methods, which show that the process may lay claim not only to practical, but to scientific, accuracy:

* If much free CO_2 is present, the experiment must be repeated, running in nearly the right amount at once.

Free CO_2.	Combined.	Sum.	Pettenkofer.	Gravimetric.
2·10	5·05	7·15	7·35	7·24
2·09	11·90	13·99	13·85	13·78
1·43	9·25	10·68	10·7	10·63
2·00	6·60	8·60	8·55	8·33
11·35	6·77	18·12	18·12	
5·67	3·38	9·05	9·06	

The formulæ in the case of waters alkaline to phenolphthalein have not been verified in this way, and must therefore be accepted with caution.

As the method depends for its accuracy on the exact neutrality of the bicarbonates to phenolphthalein, which has recently been challenged by Küster (*Zeit. f. Anorg. Chem.*, B. XIII., s. 127, October, 1896), I thought it necessary to repeat his experiments. Küster affirms that the neutrality of sodium bicarbonate is only approximate, this salt being slightly alkaline to the indicator. He states that on titrating a solution of sodium carbonate with an acid, the pink to phenolphthalein does not vanish exactly at half the quantity required with methyl orange, but much later, 2 per cent. more acid (reckoned on the methyl orange titration) being required. Although a loss of CO_2 during the titration of a $\frac{N}{2}$ solution in an Erlenmeyer flask would account for this phenomenon, he states that this cannot be the cause, since by "a somewhat careful working one can see no trace of carbonic acid being evolved from the solution," and he expresses his conviction that the explanation is a totally different one, lying in theoretical considerations which he elaborates at considerable length. This is certainly most unconvincing, and contrary to all my experience. In my experiments the carbonate was prepared in different ways: twice recrystallized and dissolved without ignition, ignited at a dull red heat, and also dried at 150° C. The carbonate was dissolved in well-boiled water, generally neutralized together with the solution of the indicator by means of a few drops of $\frac{N}{100}$ baryta, and made up to 100 c.c. The acid was added from a verified burette with a long capillary spit reaching nearly to the bottom of the tall narrow cylinder in which the liquid was titrated with continual stirring by a circular glass rod, which was never lifted above the surface of the liquid. In this way the formation of bubbles and loss of carbonic acid was as far as possible prevented.

The carbonate was also dissolved in enough water to make the solution $\frac{N}{2}$, and titrated by the same apparatus without further dilution, as also in an Erlenmeyer flask with the ordinary burette as carefully as possible. The following table gives the results:

Methyl Orange.	Methyl Orange × ½.	Phenol-phthalein.	Difference per Cent.	Remarks.
28·55	14·27	14·32	+·17	Soda twice recrystallized. Vol. 100 c.c.
28·57	14·28	14·27	−·03	
25·80	12·90	12·95	+·19	Ordinary soda ignited in muffle. Diluted.
25·85	12·92	13·00	+·27	
39·05	19·52	19·45	−·18	Twice recrystallized. Dried at 150° C.
22·85	11·42	11·60	+·70	,, ,, ,, ,, Not diluted.
28·55	14·27	15·20	+3·26	,, ,, Ordinary titration.

It is thus shown that, with proper precautions to avoid loss of carbonic acid, the pink of the phenolphthalein vanishes exactly at half the quantity required with

methyl orange within the limit of experimental error—that is, under 0·2 per cent. on the carbonate present. It is also shown that by working without dilution and other precautions, loss of carbonic acid of from 1 to 3 per cent. can easily occur, so that Küster's results are fully explained, and the neutrality of sodium bicarbonate vindicated.

As regards the utility of determining the carbonic acid in water, I would make the following observations: The interpretation of the results of water analysis, especially of the organic matter and nitrogen compounds, depends entirely on the origin of the supply—whether upland surface, mixed water from cultivated ground, deep or shallow well, the calcareous and pervious nature of the strata, etc. Now, the nature and amount of the carbonic acid is highly characteristic of waters from these different sources. In upland surface waters both the free and combined carbonic acid are characteristically low. In mixed water from cultivated land the free carbonic acid is low, and the combined generally moderate, while free carbonic acid over 0·5 per 100,000 is usually characteristic of water of underground origin. Its amount is, as a rule, greater in deep wells than in springs, and closely related to the porosity of the strata. Much fixed carbonic acid is also indicative of ground water, and related to the calcareous nature of the strata—a fact of importance in regard to the degree of nitrification. Many cases will occur to the experienced analyst in which these determinations will guide him in that most difficult task—the interpretation of the results of water analysis. Especially valuable in this connection is a determination of the free oxygen, which can now be rapidly and accurately made by the iodometric method of Ludwig Winkler. The amount of free oxygen is often distinctly correlated to the amount of free carbonic acid, varying in the opposite direction. Independently of these considerations, the carbonic acid is of importance in regard to the hardness of the water and the possibility of softening it, the free carbonic acid being as important in Clark's process as the combined and half-bound. Again, as regards the action on lead, the amounts of free and combined carbonic acid are, I believe, the chief factors.

Finally, I would draw attention to the not infrequent presence in natural waters of such as are alkaline to phenolphthalein, and therefore contain less carbonic acid than is required to form bicarbonates. The usual idea that a water which is strongly alkaline after boiling must contain alkaline carbonates is incorrect; the carbonates of lime and magnesia, especially the latter, are soluble as such in water, and exhibit an alkaline reaction with phenolphthalein. These alkaline waters are usually surface waters, or those containing magnesium carbonate, which have been exposed to the atmosphere. Sea-water is a typical example. I first met with this curious fact of the alkalinity of sea-water in the neighbourhood of Swansea, and my friend, Mr. J. E. Clennell, has had the kindness to test it for me at various points in the Atlantic, both north and south of the equator, with the result that the water was always alkaline to this indicator (strongly in the open sea, faintly near land), and therefore always devoid of free carbonic acid.

I had the opportunity of investigating a case of a fresh water of this kind in a reservoir supplied by a stream fed by springs, and considered this of sufficient interest to examine more closely. The streams entering and leaving, and the water of the

reservoir itself, were examined at intervals of a week, the temperature of the air and water and the degree of saturation with oxygen being also followed. This is of interest in connection with the fact previously observed by me, that water may be, and frequently is in Nature, supersaturated with oxygen to a very considerable extent; that is, may contain much more oxygen than is theoretically possible according to its coefficient of solubility at the temperature, even when exposing a large surface to the air. The temperature of the air was practically the same as that of the water at all depths. The stream entering contained a fair amount of free carbonic acid, and was generally nearly saturated with oxygen at the temperature of the air or water. In spite of this, on the first two occasions the water at the surface of the reservoir was alkaline to phenolphthalein and devoid of free carbonic acid. At the same time it was supersaturated with oxygen, the amount corresponding to a temperature some 5 degrees below that of the water. The water of the stream flowing out always contained a trace of free carbonic acid, and was practically saturated with oxygen at the temperature of the air and water.

On the following week the water of the surface had become acid to the indicator, containing about 0·4 parts per 100,000 of free carbonic acid, and was now deficient in oxygen, being saturated with the gas at about 5 degrees above the atmospheric temperature.

A week later the water had again become alkaline to phenolphthalein, and had reverted to a condition of supersaturation with oxygen to the extent of 7 degrees. A sample from a depth of 10 feet below the surface, however, contained at the same time as much as 0·7 parts of free carbonic acid, and was deficient in oxygen, being saturated at no less than 15 degrees above the temperature of the water, which was the same at that depth as at the surface. At the same time the distribution of chlorine and of combined carbonic acid was quite uniform, showing that the diffusion of gases must be much slower than that of salts in solution. The combined carbonic acid of the reservoir was considerably higher than that of the stream supplying it.

Discussion.

The President having invited discussion,

Dr. Rideal said he was sorry Mr. Seyler seemed to think that his paper in the *Chemical News* had not been read or appreciated. At the time of the publication of that paper he (Dr. Rideal) had taken note of it, and a student working in his laboratory at the time had repeated the work, and obtained satisfactory results. This mixed titration with methyl orange and phenolphthalein had proved useful to him in the examination of sewage-contaminated waters, in which the increased amount of carbonic acid was a measure of the amount of organic matter present in solution; it also threw a good deal of light on the variations in the chief constituents of sewage undergoing bacteriological treatment. Mr. Adeney, of Dublin, had some two years previously published a long monograph, in which the subject of the gases in water—viz., carbonic acid and oxygen—was dealt with at some length. Mr. Adeney had calculated the ratio of the oxygen to the carbonic acid much in the same way as Mr. Seyler had done in the case of the reservoir waters referred to in the

paper, and had drawn very important conclusions from his results. Mr. Adeney's task, however, had been a very laborious one, inasmuch as he had pumped out all the gases and analysed them by the ordinary methods of gas analysis, whereas the methods of estimating the dissolved oxygen and carbonic acid used by Mr. Seyler afforded a quick and ready means of arriving at the ratio between the two, and the conclusions were just as valuable as those obtained by the more laborious method. He might mention that only the previous day he had had to examine a mixture of caustic soda, sodium carbonate, and sodium silicate, and had got out his results by titrating with normal acid (using phenolphthalein as a first indicator, and finishing off the titration with methyl orange), calculating the total alkalinity in the two forms of sodium hydrate and sodium carbonate, and then determining the silica in another portion gravimetrically, calculating the percentage of sodium silicate, and deducting that from the alkalinity as sodium carbonate, thus getting the three determinations required. It had occurred to him, when Mr. Seyler was mentioning some of the methods he had been examining, that the discrepancy between the methyl orange titration and the amount of carbonic acid actually present might be due to the presence of sodium silicate in the mineral waters investigated.

Mr. BERTRAM BLOUNT inquired whether he was right in understanding that when the author said that sea-water was alkaline to phenolphthalein he meant that when neutral phenolphthalein was added a pink colour was obtained. If so, he thought that was a very interesting fact. It seemed to him that the practice of quoting analytical methods by the names of their authors rather than according to the principles upon which they were based was to be deprecated. It was almost impossible to carry in one's mind the multitude of names which it was thus rendered necessary to remember. The method, for instance, used in this investigation for the determination of oxygen was perfectly unfamiliar to him by the name of its author, though he gathered that it was of a similar nature to one (devised at an earlier period by Dr. Thresh) depending on the use of nitrous acid as a carrier for oxygen, which possessed the advantage that the danger of oxygen escaping during the process of titration into the neutral atmosphere above the water being titrated was removed. The time occupied was also much shortened. Unless some process of this kind were used, he did not think that oxygen determinations in water could be looked upon as possessing much real value.

Mr. ALLEN inquired whether the author had any actual evidence of the existence of bicarbonate of calcium. For his own part, he was very sceptical on this point. It was interesting theoretically, and no doubt convenient in practice, to make use of the expression "half-combined carbonic acid," but he had grave doubts as to the existence of such a body as bicarbonate of calcium. Some years ago a series of experiments had been made under his supervision, in which an attempt was made to demonstrate the existence of bicarbonate of calcium, but all that was arrived at was the fact that the proportion of carbonic acid requisite to keep the calcium carbonate in solution varied according to the extent to which the liquid was diluted. He raised this question from a theoretical point of view; it did not affect the practical accuracy of the results. He could fully endorse what Mr. Seyler had said as to the impracticability of precipitating the whole of the carbonate of calcium or carbonate of mag-

nesium in water by boiling. The amount which remained in solution was, however, very erratic.

Mr. HEHNER desired to reiterate Mr. Allen's remarks, which in fact comprised all that he himself wished to say. He also had made experiments with a view to ascertaining whether a neutral solution at ordinary temperatures could contain bicarbonate of calcium in the ordinary chemical sense, and had also failed to establish the existence of this body. He thought it might be probable, however, that at some temperature lower than the ordinary such a substance would exist. He did not himself quite see the object of going into the differentiation of the "half-combined" and fully-combined carbonic acid. With regard to the subject of dissolved oxygen, the diagram exhibited was exceedingly interesting. Might not the supersaturation with oxygen be due to algæ, which decomposed the carbonic acid and apparently liberated oxygen under the influence of light, since the phenomenon occurred near the surface.

Mr. A. C. CHAPMAN remarked that Mr. Allen and Mr. Hehner might equally extend their scepticism to the existence of calcium bisulphite, the evidence for the existence of both compounds being of an analogous character. In regard to the bicarbonate, the experimental results which had been obtained were not by any means conclusive as to its existence. A point incidentally referred to by the author, which was of some importance in connection with water analysis, and more especially so in the case of water containing a large proportion of alkaline chlorides, was the marked solubility of magnesium carbonate. In the analysis, for example, of London tertiary waters, which often contained a good deal of common salt, it was usual in the estimation of the alkaline carbonates to find considerable quantities of magnesium carbonate dissolved. The author's method would, of course, not apply to those waters (which, however, were not very numerous) in which organic acids of a peaty character were present.

Mr. RICHMOND said he remembered reading a paper in which it was shown that if a water saturated with oxygen at say 10° C. was cautiously raised to 15° C. without shaking or agitation, it would retain practically the whole of the oxygen, and be supersaturated. It had occurred to him on seeing Mr. Seyler's diagram that probably the water would be subjected to a good deal of agitation while running into the reservoir, and would absorb oxygen; this agitation would cease after the water had finished flowing into the reservoir, and a rise in temperature might conceivably take place unaccompanied by any diminution in the proportion of dissolved oxygen.

The PRESIDENT said that the interesting nature of the discussion in itself constituted a vote of thanks to Mr. Seyler, whom he would ask to kindly make such reply as was necessary.

Mr. SEYLER, referring to Dr. Rideal's remarks, said that he had read Mr. Adeney's paper with much interest, but the apparatus required was too expensive, and the operations too lengthy for ordinary use. He had given some examples of the application of the titrimetric method to sewage in his papers in the *Chemical News*, but confessed to some disappointment with the results in this case, as there were several interfering factors. Phenolphthalein was so much affected by ammonia that he was afraid the presence of this body in sewage might affect the results. This

difficulty might possibly be overcome by using tropæolin 000, which behaved exactly like phenolphthalein, but as far as he knew was not affected by ammonia. He had found large quantities of butyrates in sewage, and these were alkaline to methyl orange almost to the same extent as carbonates. It was quite true that the presence of silicates was a disturbing factor. In this connection it was of interest that Kippenberger had shown silicic acid to be alkaline to methyl orange—slightly, it was true, but distinctly. He (Mr. Seyler), however, thought that the difficulty was not of practical importance. With regard to the question raised by Mr. Blount as to Ludwig Winkler's method, he thought it was sometimes useful to refer to methods by their authors' names. In this method the source of inaccuracy mentioned by Mr. Blount was avoided, as in the process devised by Dr. Thresh, the oxygen carrier being, however, manganese hydrate instead of nitric oxide. The only objection to the method was the fact that sewage often absorbed iodine; but this could probably be avoided by titrating separately and deducting the iodine absorbed in this way. With regard to the scepticism which had been expressed as to the existence of calcium bicarbonate, he thought that the experiments on which such scepticism was based must have been very inconclusive. He thought that there could be no better proof of the existence of calcium bicarbonate than the figures which he had written down—the agreement would be impossible if calcium bicarbonate did not exist in the waters. Shortly before coming to town he had prepared a solution of calcium bicarbonate in the following way. He took a fairly strong solution of carbonic acid in water, and added lime-water until he got an indication of a precipitate of calcium carbonate, when he stopped the addition of lime-water, and filtered the solution (which was slightly alkaline to phenolphthalein owing to the solubility of calcium monocarbonate in water), and determined the volatile carbonic acid by Pettenkofer's method. Titration with methyl orange gave 20·7 milligrammes of carbonic acid per 100 c.c. Deducting the slight alkalinity (0·4 c.c.) for the monocarbonate present, there remained 20·3 as the amount of "half-combined" carbonic acid. Pettenkofer's method gave volatile carbonic acid 19·97. Thus, in a solution of calcium carbonate in carbonic acid neutral (like other bicarbonates) to phenolphthalein the volatile carbonic acid was shown to be approximately equal to the fixed, thus proving in his (the speaker's) opinion that the solution contained practically calcium bicarbonate. Very probably the solution on standing for some time would decompose, possibly into sesquicarbonate of calcium and free carbonic acid. There was no evidence of any abundance of algæ in the water supersaturated with oxygen. He thought that probably the explanation suggested by Mr. Richmond was the correct one. He would like to mention that the alkalinity of sea-water was enormously increased by the action of plant-life (marine algæ, etc.), which took up the "half-combined" carbonic acid, leaving magnesium monocarbonate in solution.

THE DETECTION OF GELATIN IN CREAM.

By A. W. Stokes.

(*Read at the Meeting, Nov.* 3, 1897.)

Very frequently, especially in summer, cream is thickened by the addition of gelatin to give it firmness and an appearance of richness. It is very difficult, if not impossible, to detect this by any method at present published. It is first necessary to precipitate the proteids entirely, for if any trace of these is left, this will come down afterwards and be quite undistinguishable from the gelatin. Unfortunately, most reagents which entirely precipitate proteids also at the same time bring down the gelatin.

The following method I have found to be perfectly successful, very minute quantities of gelatin being at once detected :

Dissolve some mercury in twice its weight of strong nitric acid (specific gravity 1·42); dilute this with water to twenty-five times its bulk. To about 10 c.c. of this solution add a like quantity of the cream and about 20 c.c. of cold water. Shake the mixture vigorously, leave it for five minutes, then filter. If much gelatin be present it will be impossible to get a clear filtrate. To the filtrate, or to a portion of it, add an equal bulk of a saturated aqueous solution of picric acid. If any gelatin be present, a yellow precipitate will be immediately produced. The whole operation is performed in the cold, and (if the mercury solution is ready) will not take more than ten minutes.

Picric acid will show the presence of one part of Nelson's gelatin (undried) in 10,000 parts of water. The same process would, of course, detect gelatin in milk, though I have never yet met with a sample adulterated in this manner.

A NEW "MILK-PRESERVATIVE."

By A. W. Stokes.

(*Read at the Meeting, Nov.* 3, 1897.)

Very lately a liquid called the "Rhodian Purifier" has been introduced for use with milk and other articles. It is claimed that a teaspoonful added to a pint of milk "will neutralize all disease germs—bacteria, microbes, bacilli, and other impurities—thus rendering it absolutely safe and pure, and keep milk sweet for several days in the warmest weather." This fluid was brought under the notice of several large milk-dealers, and from two of them was sent to me. I could find nothing in it but potassium nitrate and water, of the former of which there was a little over 19 per cent. Its preservative powers on milk were purely imaginary, since milk with and without this fluid (in the proportions mentioned) went sour equally soon in the month of August; while as for its "neutralizing germs," one sample was actually swarming with infusorial life, *Paramœcia* and other creatures equally large being fairly plentiful, as well as fungoid growths. After keeping the fluid for two months corked up in a

bottle, I found that the infusoria were all dead, but that living bacteria were very numerous, and also fungus spores.

The material is readily detected in the ordinary course of milk analysis. When the milk-solids are being incinerated, they deflagrate very prettily, and the ash, if taken up by a little dilute sulphuric acid, will give the nitrite reaction—*i.e.*, a blue colour with potassium iodide and starch; or in determining the fat by the Gerber, Leffmann-Beam, or Babcock process, a yellow colour is at once developed when the "preserved" milk mixes with the strong sulphuric acid. This colour, however, is not distinctive, but minute bubbles of nitrous gas are given off, which may readily be recognised by its odour. This evolution of gas makes the use of a closed tube, such as the Gerber tube, somewhat dangerous. An assistant of mine had three tubes, one after the other, burst in his hands in testing one of the samples of milk.

A NEW MILK-ADULTERANT.

By A. W. Stokes.

(*Read at the Meeting, Nov.* 3, 1897.)

Some few months ago an individual from Australia called upon a number of London milk-purveyors with a secret nostrum for concealing the addition of water to milk. He said that it had largely been used in Australia, and that 20 per cent. of water could by its use be added to milk without fear of detection. It proved on analysis to be water containing 1·96 per cent. of dextrin (British gum); it had a specific gravity of 1·0053,* and was to be added in the proportion of 4 ounces to the pint of milk. This certainly would not cover anything like 20 per cent. of added water.

As it contained a small amount of unaltered starch, it could at once be detected by the cautious addition of a solution of iodine. I have not heard of its actual use in England, but a case was quoted in a Sydney journal of a prosecution for the use of what was evidently this material, though from the evidence the analyst there was not quite clear as to the material used. I am aware that this use of British gum is not absolutely novel, but it certainly is unusual nowadays.

Discussion.

Mr. Richmond said that before making any other remark, he would like to express the pleasure he felt at seeing Mr. Stokes with the Society again. During the past two or three years Mr. Stokes had rarely been seen at the Society's meetings, and he (Mr. Richmond) felt sure that he was speaking the feeling of the meeting in expressing pleasure at seeing him. He also had met with the Rhodian preservative, and had made a full analysis of it, finding it to consist of a somewhat impure solution of potassium nitrate. He had also examined some other new preservatives, one of which contained potassium nitrate, salicylic acid, and sodium chloride, in about equal parts; another consisted mainly of a solution of salicylic acid in glycerin. With regard to this latter, it was stated that after a short

* The material having commenced to decompose, the actual specific gravity does not agree with the theoretical.

time it became impossible to detect its presence, although, as far as he knew, he had never failed to detect it in any sample containing it. He would like to ask Mr. Stokes whether he had attempted to apply his method to the estimation of the percentage of gelatin in cream. One of the first questions that a public analyst would be asked, if cross-examined in a case of this kind under the Sale of Food and Drugs Act, would be as to the proportion of gelatin present, and he (the speaker) thought there would be a considerable chance of a case falling through if the analyst was unable to say. There were, of course, a number of obvious methods by which the percentage of gelatin could be determined. It would probably be simplest to estimate the nitrogen in the filtrate from the mercuric nitrate solution, or it might possibly be done by polarization.

Mr. BODMER inquired whether, in testing for dextrin, it was necessary to coagulate the milk and test the serum, or whether operating on the original milk was sufficient to detect the quantity usually added.

The PRESIDENT said that Mr. Richmond had anticipated him in expressing pleasure at seeing Mr. Stokes with the Society again. It was a long time since Mr. Stokes had come to read a paper before them—almost as far back as the introduction of the Werner-Schmid process, which was very ancient history indeed.

Mr. STOKES said that he had not attempted to apply the method to quantitative estimations. Although the occurrence of gelatin in samples of cream was so frequent that the practice of adding it appeared to be systematic, its proportion was always very small. A mere fractional percentage was apparently sufficient to impart the apparent stiffness, which was the object of the admixture. In testing for dextrin, it was advisable to work upon the original milk, but care was necessary, as very little starch was left unchanged, and it was very easy to miss it if either too much or too little iodine were added.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

The Amount of Water in Raw Coffee. B. Niederstadt. (*Forsch. Ber.*, 1897, iv., 141.)—With the object of determining the average percentage of water in raw coffee as put upon the market, the author examined samples of several different kinds. These were dried to constant weight at 105° C., and gave the following results: Santos I., 13·33; Santos II., 12·20; Santos III., 11·23; Santos IV., 14·50; Bahia, 8·54; Menado, 10·72; Java, 10·75; Columbia, 10·00; Costa Rica, 10·62; Guatemala, 10·18; and Santos V., 9·45; the mean being about 11 per cent.

C. A. M.

The Composition of Potatoes. Balland. (*Jour. Pharm. Chim.*, 1897, vi., 298-300.)—The analyses of a large number of the principal varieties gave the following results expressed as percentages:

	Water.	Nitrogenous Substances.	Fat.	Sugars and Starches.	Cellulose.	Ash.
Normal state: Minimum ...	66·10	1·43	0·04	15·58	0·37	0·44
Maximum ...	80·60	2·81	0·14	29·85	0·68	1·18
Dried: Minimum	—	5·98	0·18	80·28	1·40	1·66
Maximum	—	13·24	0·56	89·78	3·06	4·38

The proportion of water is independent of the size of the potato, and of the variety, and appears to depend on the nature of the soil. The ash usually contains traces of manganese. The total acidity varies from 0·072 to 0·250 per cent.

C. A. M.

The Composition of Haricots, Lentils, and Peas. Balland. (*Jour. Pharm. Chim.*, 1897, vi., 196, 197.)—The following table gives the percentage results of the author's analyses:

	Haricots.		Lentils.		Peas.	
	Minimum.	Maximum.	Minimum.	Maximum.	Minimum.	Maximum.
Water	10·10	20·40	11·70	13·50	10·60	14·20
Nitrogenous substances	13·81	25·46	20·42	24·24	18·88	22·48
Fat	0·98	2·46	0·58	1·45	1·22	1·40
Sugars and starches	52·91	60·98	56·07	62·45	56·21	61·10
Cellulose	2·46	4·62	2·96	3·56	2·90	5·52
Ash	2·38	4·20	1·99	2·66	2·26	3·50

In the case of lentils, the Egyptian varieties are the richest in nitrogen, whilst the minimum of nitrogen and maximum of fat in the above table are found only in large Spanish lentils. Peas have the highest proportion of nitrogen before reaching maturity. Haricots, lentils, and peas all have about the same amount of acidity as beans, and they alter but little in their chemical composition even when kept for a long time. They absorb a considerable quantity of water—up to 100 per cent. of their weight in twenty-four hours, when first gathered, but this proportion gradually diminishes on keeping.

C. A. M.

On the Ash of Spices. A. Rau. (*Zeit. für öffent. Chemie*, iii., 439.)—A large number of samples of black and white pepper, cinnamon, pimento, and cloves was examined. The samples, first cleaned from earth and sand by sifting, furnished the following results:

Black Pepper.

212 samples were examined. The average ash amounted to 6·35 per cent., the maximum to 7·43 per cent.

43 samples contained between 5 and 6 per cent.
143 ,, ,, ,, 6 and 7 ,,
26 ,, ,, over 7 per cent.

Cinnamon.

142 samples were examined. The average ash amounted to 5·54 per cent., the maximum to 7·60 per cent.

30 samples contained between 4 and 5 per cent.
72 ,, ,, ,, 5 and 6 ,,
40 ,, ,, ,, 6 and 8 ,,

WHITE PEPPER.

155 samples were examined. The average ash amounted to 4·00 per cent., the maximum to 4·95 per cent.

60 samples contained between 3 and 4 per cent.
99 ,, ,, ,, 4 and 5 ,,

PIMENTO.

84 samples were examined. The average ash amounted to 6·38 per cent., the maximum to 8·35 per cent.

30 samples contained between 5 and 6 per cent.
53 ,, ,, over 6 per cent.

CLOVES.

78 samples were examined. The average ash amounted to 6·94 per cent., the maximum to 7·65 per cent.

45 samples contained between 6 and 7 per cent.
33 ,, ,, ,, 7 and 8 ,, H. H. B. S.

The Detection of Artificial Colour in Sausages. H. Weller and M. Riegel. (*Forsch. Ber*, 1897, iv., 204, 205.)—In the examination of a large number of different kinds of American sausages, the authors met with three samples which were of a suspicious colour, and from which the colouring matter could be extracted by digestion with glycerin and water, with alcohol, with amyl alcohol, and with ether, all the solvents being coloured from light red to deep red. On extracting the meat with acidified glycerin and water according to Bremer (ANALYST, this vol., 216), a bright red solution was obtained, but this, when evaporated on the water-bath after the addition of ammonia, remained unchanged. The coloring matter also dissolved readily in acidified amyl and ethyl alcohols, but on evaporating the solution in contact with wool fibre it was not possible to fix the colour in the wool, even in the presence of aluminium salts.

Since the sausages were strongly impregnated with salts, the authors considered it probable that the coloring matter was produced by the action of a salt on the blood-colouring matter, and their experiments confirmed this. It was found that flesh containing blood, when dried with sodium chloride, potassium chloride, sodium nitrate, sodium phosphate, or mixtures of these, yielded only minute traces of colour to the solvents. But, on the other hand, deep-red solutions were obtained from flesh containing blood which had been dried with potassium nitrate; and these behaved in the same way as the colored solutions obtained from the sausages.

From this it appeared that a chemical change of the oxyhæmoglobin had taken place during the drying with potassium nitrate, and this view was confirmed by the spectroscope, the acidified glycerin solution diluted with water giving a spectrum similar to that of methæmoglobin. After the addition of ammonium sulphide, a broad absorption band appeared at 52, and a narrower one at 64—evidently the spectrum of reduced methæmoglobin which has not hitherto been described. This

spectrum was identical with that of hæmoglobin, the formation of which was to be expected on treating methæmoglobin with ammonium sulphide.

It was further proved that the alteration of the oxyhæmoglobin was not caused by the action of the flesh fibrin brought into solution by the nitre, and it appeared to be a special characteristic of swine's blood hæmoglobin. It is well known that the oxyhæmoglobin of the blood of different animals differs considerably in composition, crystalline form, solubility, etc.; and this is in keeping with the fact that in one experiment in which calf's blood was dried with nitre, only very slight traces of colour could be extracted after two days' treatment with ether in a Soxhlet extractor. The fibrin from normal venous blood was readily soluble in a solution of nitre, whereas that from arterial or unhealthy blood, especially in the case of the ox, was frequently insoluble.

Hence it follows that the process recommended by Bremer (*loc. cit.*) can only be relied upon when it is possible to precipitate the colouring matter from its solution as a lake, and identify it chemically or spectroscopically. But since many vegetable colouring matters, which are soluble in water, cannot be precipitated in the form of lakes, whilst they are insoluble in amyl or ethyl alcohols, Bremer's method, like the others, may often fail. A microscopical examination, too, may be inconclusive when the sausage has been colored with an aqueous extract of a vegetable coloring matter thoroughly distributed, and in such cases the reactions given by the aqueous extract with iron chloride, lead acetate, calcined magnesia, manganese peroxide, sodium bicarbonate, etc., may give indications. The official method of the Berlin Police Council—viz., extraction with glycerin and water in the water-bath for fifteen minutes, or digestion in the cold with alcohol—is regarded by the authors as absolutely useless in the light of the experiments described above. C. A. M.

A Qualitative Test for Iodine in Cod-Liver-Oil and other Organic Preparations. A. Seyda. (*Zeit. für. öffent. Chemie*, iii., 359.)—Twenty grammes of cod-liver-oil are heated with 40 grammes of powdered sodium hydrate in a nickel basin for about eight hours, being meanwhile stirred from time to time with a spatula. The residue is dissolved in 400 c.c. of water in a beaker, and the particles of carbon filtered off by suction through a Watt's porcelain filter. The clear filtrate is then heated, and carbonic acid gas passed through it, until a trial portion, on treatment with excess of barium chloride, yields a neutral filtrate after boiling. The fluid is then cooled, and an equal volume of 96 per cent. alcohol added. The fine crystals of sodium carbonate which separate are removed by filtration through a Watt's filter, and washed three times with alcohol of 50 per cent. The alcoholic filtrate and washings are concentrated in a porcelain basin on the water-bath, the solution transferred to a platinum basin and cautiously evaporated, until a pure white residue is obtained. After cooling, this residue is dissolved in water, 5 c.c. of a very dilute solution (about 0·01 per cent.) of potassium nitrite and about 10 c.c. of chloroform are added, the mixture shaken, and finally treated with an excess of dilute sulphuric acid. The mixture is now again well shaken, and then allowed to stand for a few hours to settle clear. Finally, the chloroform is removed with a pipette and filtered

through a dry filter into a test cylinder for colour observation. If an equal quantity of pure chloroform be placed in another similar glass side by side with it, the violet colour (even if very faint) will be plainly discernible by contrast. H. H. B. S.

TOXICOLOGICAL ANALYSIS.

A New Method for the Determination of Chloroform in Post-mortem Examinations. A. Seyda. (*Zeit. für öffent. Chemie*, iii., 333.)—This is a colorimetric method based upon the well-known reaction of chloroform with soda and resorcin. The following solutions are prepared:

1. 1·4 grammes of pure chloral hydrate (corresponding to 1 gramme chloroform) is dissolved in 1 litre of water, and 100 c.c. of this solution are made up to 1 litre. This diluted solution will, therefore, correspond to 1 part of chloroform in 10,000, or 0·1 milligramme in 1 c.c.

2. A 10 per cent. aqueous solution of resorcin.

3. A 25 per cent. solution of sodium hydrate.

The determination is carried out as follows:

The chloroform having been extracted from the organs under examination by distillation in a current of steam, the distillate is made up to 50 c.c., and 10 c.c. transferred to a test cylinder, with 2 c.c. of resorcin solution and 1 c.c. of soda, and the whole heated to 80° C. by submersion in a water-bath.

Five comparative test solutions are now prepared in uniform glasses with 1, 2·5, 5, 7·5, and 10 c.c. of chloral hydrate solution respectively, whilst another is prepared with 2 c.c. of resorcin solution and 1 c.c. of soda. All these are made up to the same volume, and suspended in the water-bath. After heating for ten minutes, the glasses are removed from the bath, and the colours of the solutions compared.

H. H. B. S.

ORGANIC ANALYSIS.

A Characteristic Reaction of Cotton-Oil. G. Halphen. (*Jour. Pharm. Chim.*, 1897, vi., 390-392.)—In a former paper (ANALYST, xix., 283) the author stated that the zinc salts of the fatty acids of cotton-oil obtained from their solution in carbon bisulphide had a reddish-orange colour. He now finds that the same reaction is obtained by the action of carbon bisulphide on the oil itself, and that the production of the colour is accelerated by heat, by the presence of free sulphur in the sulphur chloride, and by the addition of a common solvent, such as amyl alcohol. The test is applied by mixing 1 to 3 c.c. of the oil under examination with equal volumes of amyl alcohol and sulphur chloride, containing about 1 per cent. of free sulphur, and immersing the test-tube in boiling brine for ten or fifteen minutes. If no red or orange colour is produced, another 1 c.c. of the carbon bisulphide is added; and if after five or ten minutes' heating the result is still negative, the addition of 1 c.c. is repeated.

The coloration is not of equal intensity with all cotton-oils, but varies according

to their previous treatment, though in all cases it is pronounced. By means of this reaction the author was able to detect 5 per cent. and less of cotton-oil in different mixtures. C. A. M.

On Illipè-Nut Fat. **H. Becker** (*Zeit. für öffent. Chemie*, iii., 545).—The fat expressed from the Illipè-nut has been imported into Europe from the Dutch East Indies for the past eighteen or twenty years in ever-increasing quantities. It is used principally in conjunction with palm-kernel oil in the manufacture of candles. A sample submitted to examination gave the following results:

Specific gravity at 100° C.	0·8854
Saponification number of the fat	194·04
Saponification number of the fatty acids	206·0
Iodine number of the fat	29·93
Iodine number of the fatty acids	31·64
Melting-point of the fat	35·5°–36·5° C.
Melting-point of the fatty acids	54·5°–55·5° C.
Solidification-point of the fat	24·6° C.
Solidification-point of the fatty acids	52·5° C.
Unsaponifiable	0·397 per cent.
Reichert-Meissl number	1·23
Free acid	17·245 per cent.
Mineral matter	trace

The fat was readily soluble in ether, partly soluble in cold alcohol, and readily soluble in hot alcohol, though separating out again on cooling. It was also readily soluble in chloroform, benzol, and petroleum spirit. H. H. B. S.

The Detection of Urobilin and Biliary Pigments in Urine. **E. Lepinois.** (*Jour. Pharm. Chim.*, 1897, vi., 389, 390.)—The detection of urobilin by itself is comparatively simple, but when the urine also contains biliary pigments, the results are much more uncertain. The usual method is to precipitate all the urinary pigments, with ammonium sulphate added just to the saturation-point of the liquid which has been slightly acidulated with sulphuric acid. The precipitate is collected and treated with absolute alcohol, and the solution thus obtained gives a spectrum characteristic of the pigment, and fluoresces on the addition of zinc chloride and ammonia in excess. Instead of this process, the author has for some time past used the following modification, which he recommends as more simple, delicate, and less tedious: 5 c.c. of a 10 per cent. solution of zinc chloride containing just sufficient hydrochloric acid to make the liquid clear are mixed with 20 c.c. of the urine, 3 to 4 c.c. of dilute ammonia (1 : 4) added, and the precipitate filtered off. The alkaline filtrate is fluorescent in the presence of urobilin, whilst the other urinary pigments remain on the filter more or less combined with zinc. In addition to the fluorescence, the solution will show the spectrum either of normal urobilin (urochrome) or of the abnormal urobilin of febrile urine.

Any biliary pigments present can be detected by mixing the precipitate with

several c.c. of water and dissolving it in acetic acid. This solution gives Gmelin's reaction with nitric acid containing nitrous acid as well as does the original urine.

The author objects to Deniges' recent proposal to use mercury salts as the means of separation, on the ground that it is less sensitive than the zinc chloride method, and that the solution of urobilin so obtained does not fluoresce. C. A. M.

Iodine Derivatives of Casein. **A. Siebrecht** (*Berichte*, 1897, p. 1824.)—Compounds of iodine with the numerous albuminoids and their immediate derivatives, the albumoses and peptones, can be readily formed by the following method.

Casein Periodide.—An intimate mixture of 80 grammes of casein and 20 grammes of iodine is gradually warmed on the water-bath under constant stirring. The resultant brown powder is then extracted with water-free ether in a Soxhlet apparatus for a few hours, when the iodine compound is left, which, after being air-dried, contains 17·8 per cent. of iodine. Its composition is, within very narrow limits, constant. Prepared in this way, casein periodide forms a yellow powder, little affected by cold water, but soluble in hot dilute alcohol, from which it is deposited in brown flakes as the solution cools. The compound can also be formed by boiling casein and iodine together in 70 per cent. alcohol; the casein dissolves, and on cooling the casein periodide is precipitated. A portion of the iodine appears to be in a loose state of combination; for, on treatment with an alkaline thiosulphate, the compound is decolorized, and after having been washed on the filter, dehydrated with alcohol and ether, casein iodide remains. This latter compound consists of a white powder, insoluble in the ordinary media. It has, like casein, the character of an acid, dissolving readily in an alkaline solution, from which, on acidulation, it is precipitated in an unaltered condition. Casein iodide contains phosphorus and sulphur, and can be distinguished from casein by its insolubility in sodium sulphite solution. It contains an average percentage of 5·7 of iodine.

Another compound, which the author terms "caseojodin," can be prepared by heating 100 grammes of casein periodide with 2 litres of 10 per cent. sulphuric acid for two hours on the water-bath. The reddish-brown powder formed is then filtered off, dissolved in a dilute alkaline solution, precipitated by the addition of acid, filtered off, and boiled with 70 per cent. alcohol, from which, on cooling, it is precipitated as a white, flocculent precipitate. After further purification it is obtained as a white powder, which contains, on the average, 8·7 per cent. of iodine. It is proposed to use this last preparation medicinally. W. J. S.

The Analysis of Gutta-percha. **J. A. Montpellier.** (*Rev. de Chim. Indust.*, 1897, viii., 300-302.)—Gutta-percha is obtained from the *Isonondras percha* in a similar manner to caoutchoue, and has more recently been prepared by extracting the leaves of the tree with a solvent such as benzene. It contains three proximate constituents, first isolated by Payen in 1851, to which have been given the names *gutta*, *fluavile*, and *albane*. The author gives the following scheme for its analysis:

Estimation of Gutta and Resins.—From 0·5 to 1 gramme of the finely-divided sample is placed in a weighed filter-paper, supported by a perforated platinum cone

which is suspended (its point in the liquid) in a flask connected with a Soxhlet apparatus. Here it is extracted with boiling alcohol for five or six hours, after which the cone is transferred to the Soxhlet extractor, and the extraction continued for the same length of time. The resins (fluavile and albane) dissolve in the boiling alcohol, whilst the gutta and impurities remain in the filter-paper, and are dried at 100° C. in a current of carbon dioxide and weighed. The impurities are determined separately and deducted.

Separation of Albane and Fluavile.—This can only be done incompletely, but an approximate determination of the amount of each may be made by extracting 5 grammes of the sample with alcohol as above, and evaporating the alcoholic extract until the albane begins to separate out. On cooling, the fluavile remains in solution, and the albane, which has crystallized out, is collected on a weighed filter, dried at a low temperature, and weighed.

Estimation of Water.—One gramme of the gutta-percha is dried at 100° to 110° C. in a current of carbon dioxide for six to seven hours.

Estimation of Impurities.—A weighed quantity (not exceeding 1 gramme) is extracted with boiling chloroform in the same way as in the determination of gutta with alcohol. This dissolves both gutta and resins, and the impurities left behind are dried in a current of carbon dioxide and weighed.

Ash.—This is determined in the usual manner. Its amount never exceeds 0·5 per cent. C. A. M.

The Volumetric Determination of the Nitro-Group in Organic Compounds. S. W. Young and R. E. Swain. (*Jour. Amer. Chem. Soc.*, 1897, xix., 812-814.)—The proposed method is based on the reduction of the nitro-group by means of stannous chloride, and titration of the excess of the latter with standard iodine, in accordance with the reactions

$$RNO_2 + 3SnCl_2 + 7HCl = RNH_2.HCl + 3SnCl_4 + 2H_2O,$$

and

$$SnCl_2 + 4I = SnCl_4 + SnI_4.$$

So far the author's experiments have been confined to dinitrobenzene, and further work is required to determine to what extent the method is generally applicable. The process was as follows:

Weighed quantities of pure dinitrobenzene were placed in Erlenmeyer flasks and dissolved in 10 c.c. of alcohol. These flasks were connected in series with a Kipp generator for carbon dioxide, and when filled with the gas the stoppers were removed, and sufficient stannous chloride solution introduced into each to reduce the dinitrobenzene and leave a slight excess. The current of gas was again passed through the flasks, which were heated on the water-bath until the reduction of the dinitrobenzene was complete. This was usually the case in one and a half to two hours. The addition of 20 to 25 c.c. of strong hydrochloric acid somewhat accelerated the reduction. The flasks were then disconnected, and the excess of stannous chloride in each titrated back with the standard iodine solution.

From the result the nitro-equivalent of the iodine solution was calculated, and

thence the percentage of nitro-group in the body. The following eight results were obtained in one series of determinations: 54·63, 54·48, 54·61, 54·40, 54·44, 54·49, 54·44, and 54·44 per cent., the theoretical percentage being 54·76.

C. A. M.

Direct Estimation of Chlorine, Bromine, and Iodine in Organic Substances. Separation of Bromine from Chlorine by Means of Permanganate. P. Jannasch and E. Kölitz. (*Zeit. anorg. Chem.*, 1897, xv., 68 and 66.)—The authors separate the halogens from the organic compound in the form of silver salts by either the Carius or lime method.

In whichever way the silver compounds are obtained, they are collected on a filter, washed, and, together with the paper, placed in a silver crucible, and fused with 5 or 6 grammes of pure caustic soda. The melt is extracted with warm water, the silver filtered off, the solution acidified with sulphuric or nitric acid, and the iodine, bromine, and chlorine finally separated from one another with thallium sulphate (I from Cl), or by the processes of distillation with acetic acid and sodium nitrite (I from Br and Cl), and with acetic acid and potassium permanganate (Br from Cl), which have been already described by Jannasch and Aschoff (*Zeit. anorg. Chem.*, 1892, i., 144, 245, and 248).

In another communication (*loc. cit.*, p. 66) the same authors call attention to the fact that this separation of Br from Cl by the action of acetic acid and permanganate cannot be effected in presence of much sodium acetate, as the latter body almost entirely prevents the evolution of free bromine. If, therefore, the original solution containing the halogens is strongly alkaline, it must first be neutralized with either nitric or sulphuric acid before the acetic acid required in the distillation is introduced.

F. H. L.

INORGANIC ANALYSIS.

Note on the Separation and Estimation of Lead, Copper and Arsenic. F. Jean. (*Ann. de Chim. Analyt.*, ii. [19], 361.)—The lead, copper and arsenic are separated from the metals of the second group thrown down in the usual manner by hydrogen sulphide. After washing the precipitate of the mixed sulphides by decantation, they are oxidized by digestion with warm sodium hypochlorite solution; the solution is then acidified with sulphuric acid, boiled to expel excess of chlorine, and the *lead* thrown down as sulphate by alcohol in the cold solution. The filtrate is boiled to drive off alcohol, sufficient ammonia added to redissolve the precipitate of copper arseniate first formed, and the *copper* titrated by sodium sulphide, the end point being indicated by the brown coloration produced by a drop of the liquid brought into contact with a drop of an alkaline solution of lead. The solution is then acidified with dilute hydrochloric acid and the copper sulphide removed by filtration; the *arsenic* is determined as arsenic acid by adding a few crystals of potassium chlorate, concentrating the solution to about 20 c.c., nearly neutralizing ammonia, adding 5 c.c. of sodium acetate, and titrating with uranium acetate

under the same conditions as are maintained in estimating phosphoric acid by the Joulie method.

By the above method 0·1212 gramme of lead was found in a mixture containing 0·1220 gramme, the whole of the copper (0·020 gramme), and 0·0370 gramme against 0·0375 gramme of arsenic was also detected. C. S.

Determination of Lead and Antimony in Tinfoil. A. Seyda. (*Zeit. für. öffent. Chemie*, iii., 364.)

I. *Lead Determination.*—Ten grammes of foil are dissolved in 25 per cent. hydrochloric acid with the aid of heat. If antimony is present to the extent of about 1 per cent., it will remain for the most part undissolved. The stannous chloride is then converted into stannic chloride by the addition to the hot solution of 25 per cent. nitric acid, which at the same time dissolves the remainder of the antimony. A slight excess of a 25 per cent. solution of soda is now added gradually to the clear fluid, which is meanwhile warmed and kept in motion until the precipitate at first formed redissolves, leaving only a slight opalescence. A small quantity of precipitated sulphur is then added to the solution, and hydrogen sulphide passed through it, until it acquires a distinctly yellow colour. After standing for twenty-four hours, the black precipitate is filtered off, and washed on the filter with solution of sodium sulphide, until a trial portion of the filtrate, after acidifying with hydrochloric acid, produces a pure white precipitate of sulphur. The washing takes a considerable time, but must be thoroughly carried out, or the tin will not be completely separated from the lead. The filter with the moist precipitate is now removed from the funnel, and carefully heated with nitric acid of 25 per cent., after which the filter is pressed together into a loose ball by the aid of a stirring rod and placed in the funnel, the nitric acid solution filtered several times through it until clear, and the ball of paper then washed, first with hot nitric acid, and afterwards with hot water, until a portion of the washings no longer gives a black precipitate with hydrogen sulphide. In this way, any lead sulphate that may be formed is completely removed from the filter. The filtrate is then transferred to a basin, about 20 c.c. of dilute sulphuric acid added, the liquid evaporated, and the lead sulphate filtered off through a porcelain Gooch crucible and weighed.

II. *Antimony Determination.*—The method proposed is an adaptation of Rose's: 5 grammes of the foil cut into strips are dissolved a little at a time in 100 c.c. strong nitric acid with the addition of 25 c.c. of water. The metastannic acid i washed out with nitric acid of 25 per cent. into a porcelain basin, the acid evaporat to dryness, and the residue dried in the water-bath. It is important that the perature at which it is dried does not exceed 100° C., as the anhydrides of tin and antimony do not appear to combine with soda. The dry powder while still warm is added a little at a time to 60 grammes of sodium hydrate heated to fusion, with which it is thoroughly mixed by means of an iron spatula. Combination takes place almost immediately. The fused mass is allowed to cool to about 100° C., and is then broken up and dissolved by the aid of heat in about 700 c.c. of water. The turbid fluid is cooled, transferred to a beaker, and mixed with one-third of its volume of alcohol of

96 per cent. After standing for twenty-four hours, the precipitate is filtered off by decantation, using a mixture of two volumes of alcohol and one volume of water for washing out the last portions from the beaker.

In place of washing the precipitate with dilute alcohol, which causes the loss of some of the antimony, a second fusion with sodium hydrate is resorted to. This is carried out as follows: The filter with the precipitate is dried at 100° C., the precipitate is detached and the paper cut up into strips, and added to 10 grammes of fused sodium hydrate, its destruction being facilitated by the addition of a little sodium nitrate. When the paper has disappeared, the precipitate is added to the fused mass, and the fusion, solution and filtration then proceeded with as before. In order to ensure the insolubility of the sodium antimoniate, the liquid should contain about 10 per cent. of sodium hydrate and 25 per cent. of alcohol. The antimony is finally weighed as Sb_2S_3. H. H. B. S.

The Analysis of Phosphor Bronze, Phosphor Copper, Phosphor Tin, etc. **M. Wickhorst.** (*Jour. Amer. Chem. Soc.*, 1897, xix., 396-398.)

Determination of Phosphorus alone.—One gramme of the sample is treated with 20 c.c. of aqua regia (HNO_3, 15 c.c.; HCl, 5 c.c.), and after the action has ceased water is added, then ammonia in excess, and the liquid is made up to 200 c.c. Copper, lead, etc., are precipitated with sulphuretted hydrogen, the liquid filtered, and the phosphorus determined in 100 c.c. of the filtrate by precipitating in the usual way with magnesia mixture and ammonia. In very accurate work the precipitate is dissolved in hydrochloric acid, and the magnesium ammonium phosphate reprecipitated, but for most purposes one precipitation is sufficient.

Complete Analysis of Phosphor Bronze.—Half a gramme of borings are heated with 5 c.c. of nitric acid, the residue rubbed well with a rod and filtered off after the addition of a little water, and washed with water containing a little nitric acid. The filter and its contents are ignited, and the weight of residue gives stannic oxide plus phosphorus pentoxide. The residue is then fused with 0·5 gramme of sodium carbonate and 1 gramme of sulphur in a covered crucible, and the excess of sulphur expelled over a Bunsen flame. The cooled mass is dissolved in hot water, excess of ammonia added, then 1 gramme of ammonium chloride, and when cold the phosphorus is precipitated with magnesia mixture. The precipitate is collected, washed with dilute ammonia solution containing a little ammonium sulphide, dissolved in diluted hydrochloric acid, reprecipitated, and the phosphorus determined in the usual manner. The difference between the phosphorus pentoxide calculated from the result and the residue of stannic oxide plus phosphorus pentoxide gives the amount of stannic oxide.

The treatment with nitric acid does not render the whole of the phosphorus insoluble with the tin. The small amount going into solution is determined by precipitating the filtrate of a duplicate sample with molybdate solution and estimating the phosphorus in the precipitate by one of the usual methods. This phosphorus is added to that obtained above. The filtrate from the stannic oxide plus phosphorus pentoxide is neutralized with ammonia, 5 c.c. of nitric acid added, then made up to 150 c.c. and transferred to a large platinum dish. In this a platinum foil about

2 inches square is suspended, and an electric current* passed through so as to precipitate the lead, as lead dioxide, on the dish, and the copper as metallic copper on the foil. The precipitates are washed well with water, dried, and weighed.

Iron and zinc may also be present. If so, the liquid is warmed, an excess of ammonium hydrate added, and then ammonium sulphide. The precipitate ignited gives iron oxide plus zinc oxide. When weighed it is dissolved in hydrochloric acid, the iron determined as hydroxide, and the amount deducted from the previous weight.

C. A. M.

A New Method for the Determination of Phosphoric Acid. Woy. (*Zeit. für öffent. Chemie*, iii. 321.)—In recurring to the subject of his recent papers on the determination of phosphoric acid as phospho-molybdic anhydride (*cf.* ANALYST, this vol., 250) the author remarks:

The methods for the precipitation of phosphoric acid by molybdenum, used up to the present, have been characterized, on the one hand, by the employment of a large excess of molybdic acid, and, on the other, by the abundant use of nitric acid. The reason for this is the peculiar behaviour of molybdic acid. It dissolves to a clear solution in water containing nitric acid, but separates out on the addition of ammonium nitrate, though the more nitric acid used, the less is the separation which takes place, in cold solutions. Consequently, strong nitric acid counterbalances the tendency of the ammonium nitrate to promote the separation of the molybdic acid. But if the precipitation is made in a strong nitric acid solution, the yellow precipitate becomes partly dissociated, the dissociation increasing or diminishing in proportion as more or less nitric acid is used. Hence, when much nitric acid is used, it is needful to employ a large excess of molybdenum to counteract the tendency to dissociation. Hundeshagen, however, has shown that, for the precipitation of phosphoric acid by ammonium molybdate, it is only needful for the molybdate to be present in the proportion corresponding to $1P_2O_5 : 24MoO_3$; and, further, that only a correspondingly small proportion of nitric acid and about 5 per cent. of ammonium nitrate are required.

Experiments based upon the foregoing considerations resulted in the adoption of a 3 per cent. aqueous solution of ammonium molybdate, which always remains clear, and may be relied upon at any time to contain the requisite proportion of molybdenum.

As working details of the method have already been published in this journal (*vide* abstract of author's former paper, above mentioned), it is only necessary to add that, as certain chlorides are found to be prejudicial to the precipitation, the author dissolves raw phosphates in sulphuric acid (taking care to prevent the gypsum formed from setting into a mass), afterwards neutralizing the portion of the solution taken with ammonia as far as is possible without causing a precipitate to fall.

H. H. B. S.

* Strength of current not given.—ABSTR.

Valuation of Phosphates according to their Citrate-Solubility. P. Wagner. (*Chem. Zeit.*, xxi., 905.)—In the official directions for working Wagner's method for the determination of the citrate-soluble phosphoric acid in Thomas phosphate, as accepted in Germany, it is stated as follows: "The phosphoric acid must be determined by the molybdate method; direct precipitation by magnesia gives high results when the percentage of silicic acid rises above a certain limit." It appears from experiments which have been recently carried out in the author's laboratory, that this obstacle to direct precipitation by magnesia has been overcome. The conclusions arrived at are as follows:

1. If the freshly-prepared citrate-extract of a phosphate be mixed with alkaline citrate solution and magnesia mixture, and stirred for the customary half-hour with the stirring machine, the precipitated ammonium magnesium phosphate will be found to be quite free from silica. It makes no difference whether the solution be filtered directly after the stirring is completed, or whether it be first allowed to stand for two hours.

2. Though the citrate extract of Thomas slag remains practically clear, however long it is allowed to stand, it nevertheless develops on standing a peculiar tendency to deposit silica on the addition of alkaline citrate, and this tendency increases from hour to hour, so that even with samples only moderately siliceous, a separation of silica takes place if the extract be allowed to stand for three hours before the addition of the alkaline citrate. When, however, alkaline citrate is added to freshly-prepared extract, no separation takes place, even if the mixture be allowed to stand for eight hours.

3. The tendency to the separation of silica is very considerably diminished by the precipitation of the phosphoric acid. In a citrate-extract three hours old, no silica was separated when the alkaline citrate and magnesia were added together and the mixture allowed to stand for two hours.

4. It follows: (*a*) that the precipitation by means of magnesia mixture should be made, if possible, in freshly-prepared extract, and (*b*) that to ensure the non-separation of silica, especially when the extract is not quite fresh, a mixture of alkaline citrate and magnesia mixture should be used to precipitate the phosphoric acid in the extract.

The mixture of alkaline citrate and magnesia mixture is prepared as follows: 200 grammes of citric acid are dissolved in ammonia solution of 20 per cent., and the solution diluted to 1 litre with ammonia of the same strength. The litre of alkaline citrate so prepared is mixed with 1 litre of the official magnesia mixture.

For the determination of the citrate-soluble phosphoric acid, 50 c.c. of extract, either freshly prepared or not more than one hour old, are mixed with 50 c.c. of the above precipitating-fluid, and the mixture stirred for half an hour with the stirring machine. If the precipitate is not filtered off immediately, it should, at any rate, not be left standing longer than one hour.

The author has submitted the above modification of his process to the consideration of the chemists of the German experimental stations (*cf.* ANALYST, April to July, 1896). H. H. B. S.

REVIEW.

THE PRINCIPLES AND PRACTICE OF BREWING. BY WALTER J. SYKES, M.D., D.P.H., F.I.C. (London: Charles Griffin and Co., Limited, 1897.) Price £1 1s.

The appearance of a work such as this serves to remind one of the enormously rapid advances made during recent years in our knowledge of the scientific principles underlying the brewing processes. On glancing through Dr. Sykes's new book, the first feeling, perhaps, is one of astonishment at the vast number of investigations which have been undertaken by men of science with the object of throwing light upon the complex changes involved in the manufacture of beer, investigations which have in some cases earned for their authors world-wide renown in scientific circles. In no other ancient industry, probably, has the transition from the darkness of empiricism to the light of science been so rapidly effected. The author rightly commences his work with a discussion of the physical principles involved in brewing operations, a matter which is frequently ignored in treatises dealing with the science of brewing. To a considerable number of brewers the expressions *density*, *specific heat*, and *latent heat*, convey no definite and clear meaning, whilst the real nature of the thermometer, and the relation between the two chief thermometric scales, are far from being clearly understood. To such Dr. Sykes's clear exposition will prove interesting and useful. The second chapter deals with the chemistry of those substances with which the brewer is chiefly concerned, and includes a short account of the construction and use of two forms of polarimeter which are best adapted for the examination of brewing materials—namely, the Laurent instrument and the half-shadow polarimeter made by Schmidt and Haensch. In this section an account is given of certain important groups of organic compounds, such as the alcohols, aldehydes, ketones, hydrazones, etc., a knowledge of which is necessary to the understanding of the constitution of the sugars. It is matter for regret that the scientific training with which the average brewer commences his brewing career is such as to render this account, clear as it is, somewhat beyond his grasp. To many, however, the addition will be very welcome. A full description of the more important carbohydrates is given, and includes an accurate account of all the most recent investigations, whilst the better known proteids and enzymes receive an amount of attention which is justified by the all-important parts they play in practice. As a minor point in nomenclature, it would appear better to employ the word "glucose" only in speaking of the commercial product, whilst referring to the carbohydrate itself as "dextrose," the former word being at the present time somewhat indefinite. It may be remarked, in passing, that the analysis of commercial glucose by Birneisel quoted on page 80 can scarcely be taken as representing the average composition of the sugar manufactured in this country. It appears to be what is often euphemistically described as a "commercial analysis" in which the presence of maltose is ignored and the increased cupric-reducing power on hydrolysis attributed solely to dextrin, which is, as a rule, present only in traces. An admirably clear account of the numerous researches which have been undertaken with the object of elucidating the changes involved in the hydrolysis of starch at the instance of diastase is given, for which alone Dr. Sykes would well deserve the thanks

of all chemists desirous of knowing to what extent this most difficult problem has been solved. A description of the hop-plant and of the various constituents of the strobiles follows. The first chapter of the second part deals with that instrument which may be described as the sheet-anchor of the modern brewer—the microscope. A short account of its various parts is given, together with some useful hints to intending purchasers, instructions for its use, and a lucid description of the simpler bacteriological methods. Perhaps no section of this work is deserving of greater praise than that treating of vegetable biology and fermentation. Starting with a description of the *Protococcus pluvialis*, as a unicellular organism which may conveniently be used for the purpose of illustrating certain important biological functions, such as *assimilation, respiration*, and *reproduction*, the author passes on to a consideration of the life history of the yeast organism, the torulæ, certain bacteria, and some common mould fungi. To describe clearly and concisely everything of importance that has been thought and done in connection with the decomposition of sugar by the yeast organism is no easy matter, and Dr. Sykes is to be congratulated on the success with which he has accomplished the task. As far as possible in chronological order, and with a due appreciation of the importance of each, one finds all the chief theories of fermentation discussed, together with an account of the many important chemical and biological investigations which led up to the brilliant work of Hansen on the production of single-species yeast and its use on a commercial scale. A short account of the structure of the barley-grain, and of the nature of the interesting changes occurring during the process of germination, is also given. The first chapter of the third part deals with the composition of natural waters and their suitability for the production of different classes of beers, the remainder of the book being devoted to the subjects of malting and brewing, considered in their more technical aspects. The chapters dealing with the construction and arrangement of brewery-plant and with the practice of brewing are such as to add greatly to the value of the book.

A chapter on the ills to which beer is heir, and five short appendices (one of which deals with Buchner's recent work on alcoholic fermentation without yeast-cells), bring this work to a conclusion. A description of the methods adopted for the analysis of brewing materials and products has been omitted, as it would, to use the author's own words, "have made the book too voluminous," and constitutes in itself "a subject sufficiently large to form a separate treatise." A careful perusal of the work under review leads one to hope that Dr. Sykes will one day give us a companion volume dealing with this branch of the subject. Every page bears testimony to the fact that no pains have been spared to render this work as complete as the present state of our knowledge permits. It will undoubtedly be of the greatest assistance, not merely to those for whom it is professedly written, but to all chemists and biologists who are interested in the numerous scientific problems which the fermentation industries present. To such it will prove not only a valuable work of reference, but will serve the still more useful purpose of directing attention to many obscure points which yet call for experimental study. The illustrations are well executed, and a complete table of contents and a good index add to the usefulness of the book.

THE ANALYST.

JANUARY, 1898.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, December 1, in the Chemical Society's Rooms, Burlington House, the President (Dr. Bernard Dyer) occupying the chair.

The minutes of the previous meeting were read and confirmed.

The President read the following list of officers for the ensuing year, as proposed by the existing Council for election at the annual meeting:

President.—Bernard Dyer, D.Sc.

Vice-Presidents (who have filled the office of President).—M. A. Adams, F.R.C.S.; A. H. Allen; Sir Chas. A. Cameron, M.D., F.R.C.S.; A. Dupré, Ph.D., F.R.S.; Otto Hehner; Alfred Hill, M.D., F.R.S.E.; J. Muter, M.A., Ph.D., F.R.S.E.; Thos. Stevenson, M.D., F.R.C.P.

Vice-Presidents (who have not filled the office of President).—A. P. Aitken, D.Sc., F.R.S.E.; W. W. Fisher, M.A.; J. A. R. Newlands.

Hon. Treasurer.—E. W. Voelcker, A.R.S.M.

Hon. Secretaries.—E. J. Bevan, Charles E. Cassal.

Other Members of Council.—Bertram Blount, Sidney Harvey, C. G. Moor, M.A., F. Wallis Stoddart, Walter J. Sykes, M.D., John White, W. C. Young.

The names of those members of the Council who do not retire this year are R. Bodmer, A. Wynter Blyth, M.R.C.S., A. C. Chapman, S. Rideal, D.Sc., J. E. Stead, J. A. Voelcker, M.A., B.Sc., Ph.D.

Mr. Leonard K. Boseley, analyst to Messrs. James Keiller and Sons, of Silvertown, was proposed for election as a Member of the Society, and Mr. — O'Shaughnessy, assistant to Mr. H. Droop Richmond, as an Associate.

The following papers were read:

"Milk Analysis and Certification." By James Edmunds, M.D.

"A Method of Estimating Tannic Acid by Means of the Polarimeter." By R. F. Wood-Smith.

"A Butter Eighteen Years Old." By E. G. Clayton.

"Note on Mineral Matter in Commercial Bleached Ginger." By E. J. Bevan.

The following gentlemen were elected members of the Society: Mr. S. H. Collins, F.I.C., Assistant Agricultural Chemist to the Indian Government; Professor James Hendrick, B.Sc., F.I.C., the University, Aberdeen; Mr. W. H. Jackson, Analyst to the West Yorkshire Coal and Iron Company; and Mr. E. H. Roberts, Analyst to the Dairy Supply Company, Ltd.

On the proposal of Mr. HEHNER, seconded by Mr. CHAPMAN, Mr. John Hughes and Mr. Bertram Blount were appointed auditors of the Society's accounts for the year.

The PRESIDENT announced that, although the Annual Dinner would take place on Tuesday, January 18, the Annual Meeting, for the election of officers, etc., would not take place until February, when it would be held in conjunction with the ordinary meeting.

AN IMPROVED MILK-SCALE.

BY H. DROOP RICHMOND.

(*Read at the Meeting, Nov.* 3, 1897.)

WHEN determining the density of milk, it is frequently a matter of convenience to make the estimation at the temperature at which the milk happens to be, instead of adjusting it to the normal temperature. When this is done, it is necessary to make a correction to ascertain the value at 60° F.

Vieth has published a set of tables (ANALYST, x. 70) founded on those of Fleischmann, and these I have found correct; numerous experiments have shown that the difference between the density at 60° F. shown by Vieth's tables, and that actually determined, very rarely exceeds 0·0002.

Seeing the favour with which slide rules are regarded at the present time, it has long been my desire to incorporate a corrector of specific gravity with the "milk-scale." I have now succeeded in doing this. On the body of the instrument the temperature is engraved, each degree of temperature being of dimensions corresponding to the increase of specific volume (specific volume of milk at 32° F. = 1); on the slide the scale of specific gravity is marked, each degree having a value inversely proportional to the increase of expansion with the specific gravity. To use the instrument, the specific gravity found (*i.e.*, the apparent specific gravity determined in glass vessels) is placed against the line 60° F. (marked with an arrow); the true specific gravity is read off against the temperature at which the determination was made.

The "milk-scale" is now made by Messrs. Baird and Tatlock, London, with the addition of the specific gravity corrector.

DISCUSSION.

The PRESIDENT said that very many analysts were already much indebted to Mr. Richmond for the time saved in calculation by the use of his milk-scale, and the introduction of the modification now described would add to their obligation.

Mr. A. W. STOKES said that the working of the scale was greatly facilitated by the use of a simple index, made by bending a flat piece of metal, a plan which he had found to answer better than any of the other devices made, which were more or less complicated.

The PRESIDENT said that an ingenious little apparatus of a nature somewhat similar to that mentioned by Mr. Stokes had been introduced some time previously

by Mr. Cassal. Among the advantages of such a device was that it prevented the temptation to make ink-marks on the scale.

[NOTE.—As the question of pointers was raised in the discussion, I may point out that the first was used by Mannheim nearly fifty years ago on the slide-rule. It was first applied to the milk-scale by A. E. Johnson, the most recent improvement being the use of a vernier instead of a pointer, as proposed by Sykes.] H. D. R.

NOTE ON THE GRADUATION OF LEFFMANN-BEAM BOTTLES.

BY G. E. SCOTT-SMITH AND A. B. SEARLE.

(Read at the Meeting, Nov. 3, 1897).

IN estimating the amount of fat in milk, we have recently been much perplexed by the occurrence of a great discrepancy between the results of the Leffmann-Beam and Werner-Schmid processes. This was the more surprising as the two methods had given us very concordant results in the past.

We first directed our attention to the reagents used. The amylic alcohol was purified by shaking with brine to remove any ethylic alcohol which might be present. It was then allowed to stand for twenty-four hours over potassium carbonate, and was then distilled. That portion distilling between 128° C. and 131° C. was used for the experiments. The sulphuric acid was found to be of the specified strength as calculated from the specific gravity (1·843). Using these purified reagents no better results were obtained.

A mixture of amyl alcohol and hydrochloric acid some weeks old was compared with a mixture prepared from the same reagents a few minutes before use. Experiments were made at the same time in which the quantity of sulphuric acid used was slightly varied, a constant volume of 15 c.c. of milk being used in each case. The volume of fat thrown up was noted after whirling one, two, three, four, and five minutes respectively, with the following results:

	Fat ; per Cent.				
	In one minute.	In two minutes.	In three minutes.	In four minutes.	In five minutes.
Using 9 c.c. H_2SO_4 and "old" amyl alcohol mixture	3·7	3·3	3·3	3·3	3·3
Using 9 c.c. H_2SO_4 and "new" amyl alcohol mixture	3·7	3·3	3·3	3·3	3·3
Using 10 c.c. H_2SO_4 and "old" amyl alcohol mixture	3·7	3·3	3·3	3·3	3·3
Using 10 c.c. H_2SO_4 and "new" amyl alcohol mixture	3·7	3·3	3·3	3·3	3·2

After whirling for one minute the separation was not sharp, as the layer of fat contained a large quantity of flocculent matter. After two minutes' whirling the separation of the fat was almost complete, and after three minutes the separations were always sharply defined. These results are satisfactory, in so far as they show

that the amount of sulphuric acid can be varied to a moderate extent without affecting the accuracy of the results.

Being convinced that our reagents were pure and that our method of procedure was correct, we attempted to find whether the source of error lay in the graduations of the bottles. We were aware that attention had been directed to the fact that it was necessary to calibrate the bottles before use, but we could not find a ready method for effecting this. As the 80 divisions on the neck of the bottle represent collectively a volume of only 1·2 c.c., the calibration is attended with difficulties which are not met with in many other cases.

We first attempted to calibrate the bottles by running in water from a fine burette, but this method was found to be useless, as an error of ± 0·05 c.c. per 10 divisions corresponded to 0·3 per cent. of fat, and in practice an error of this magnitude was unavoidable, chiefly owing to the tendency of the water to adhere to the sides of the neck of the bottle.

In later experiments proof-spirit was used, and the liquid weighed instead of being measured. In each case the bottle was filled up to the lowest division (number 80) with the spirit, and weighed carefully. More spirit was then run in from a small pipette until the liquid stood at the 70th division, when the bottle and its contents were again weighed, and this procedure was repeated at each 10 divisions until the liquid had reached the zero-mark of the bottle. This method appears to provide a ready and fairly rapid method of checking the accuracy of the graduations. It overcomes completely the difficulty due to adhesion of the liquid to the neck, without the inconvenience and necessity of whirling, with consequent liability to change of temperature and correction for expansion. If a balance turning to half a milligramme be used and the calibration conducted expeditiously, the loss of alcohol by evaporation is insignificant, and the use of mercury, with its objections, is avoided, the slightly greater accuracy obtained by the use of the latter being little or no advantage compared with the greater tediousness of the method. If the temperature of the balance-room is constant, no correction need be applied, as only the relative volumes of the graduations are required. The following are some of the figures obtained:

Weight of spirit in grammes:	1.	2.	3.	4.	5.	6.	7.	8.
80 to 70 divisions	·114	·117	·144	·141	·156	·155	·134	·150
70 to 60 ,, ...	·095	·150	·145	·149	·145	·150	·145	·129
60 to 50	·107	·102	·158	·142	·142	·150	·151	·161
50 to 40	·141	·119	·143	·131	·150	·151	·145	·145
40 to 30	·145	·149	·150	·134	·150	·134	·144	·157
30 to 20	·148	·153	·143	·150	·150	·166	·160	·157
20 to 10	·151	·147	·153	·142	·150	·151	·150	·148
10 to 0	·142	·157	·150	·158	·150	·146	·156	·150
Total weight of alcohol (in grammes)	1·042	1·099	1·186	1·147	1·193	1·203	1·185	1·197

These figures show how very imperfectly the bottles are graduated by the manufacturers, and how necessary it is to check each bottle before use if the Leffmann-Beam process is to be relied on. Thus, if No. 6 bottle were used, and the reading taken between divisions 80 and 50, the amount of fat shown would be 2·7 per cent.,

instead of the 3 per cent. actually present in the milk. In the case of bottle No. 1, if the reading were taken between the 50th and 80th divisions, a milk containing 2·3 per cent. of fat would show 3 per cent.

Bottles Nos. 3 and 5, on the other hand, are much more evenly graduated than any of the others in this series, and these two bottles have been found in practice to give fairly good results. Another set of bottles, calibrated in the same manner as the first set, showed that the scale in each was very uniformly graduated, but all the divisions were slightly too large. Hence the percentage of fat indicated was rather less than the true amount present, but the error was not sufficiently great to prevent the bottles being used.

Discussion.

Mr. A. W. Stokes agreed with the authors that the best liquid to use was alcohol, which possessed, among other advantages, that of being able to pass easily down a very narrow tube. He thought, however, that in filling the bottles with a pipette an error might arise through drops of liquid clinging to the sides of the tube, unless care was taken to get rid of such drops by rotating the bottle after the liquid had been added.

Mr. Richmond thought that alcohol was not a desirable fluid to use on account of its sensibility to changes of temperature. No provision seemed to have been made by the authors for obtaining a constant temperature. He thought it ought to be constant to a tenth of a degree, as otherwise the expansion or contraction of the alcohol would give rise to a distinct error. He had himself obtained excellent results with water. As far as he could remember, the bottle No. 3 was exactly correct, according to a specification which he had drawn up for Messrs. Baird and Tatlock, and to which all bottles supplied by that firm were made. He had found that a satisfactory method of calibrating these bottles was by means of a finely divided rule. He had not himself used the Leffmann-Beam process at all for about two years, but had previously used about two or three hundred of the bottles, and had always found them to be excellently graduated. He could not say whether they had fallen off in character; but from the results shown in the paper this would seem to be the case.

Mr. Hehner said that faulty graduation was not found merely in Leffmann-Beam bottles, but in almost every other kind of measuring instrument. He had lately checked the graduation of a number of burettes, and had found that out of a dozen, only three came up to the requirements of an ordinarily careful analyst, the other nine being from 1 to 1·7 per cent. out. Too much trust had been put in the makers of scientific instruments in this matter, and he certainly thought that every burette and pipette should be checked before being used, as had been suggested by Mr. Richmond years before.

The President said that he had no experience of Leffmann-Beam bottles, but he had used a set of Gerber bottles for a long time, and had never met with any discrepancies such as would indicate inaccurate graduation. Occasionally the results did not agree very closely, but this had generally been due to imperfect whirling before the use of the apparatus had been thoroughly mastered. It was very whole-

some indeed for papers of this kind to be brought before the Society. Most analysts had had experiences similar to those which Mr. Hehner had mentioned, and had grown cautious in accepting the graduation of the instrument makers. It was not merely in instruments for the measurement of capacity that errors were found. They were very common indeed in hydrometers, even of a fairly expensive kind, and even in thermometers, which were so very easily tested.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

The Determination of Fat in Watered Milk, Human Milk, Humanized Milk, and Condensed Milk. J. Froidevaux. (*Jour. Pharm. Chim.*, 1897, vi., 485-489.)—In the author's opinion, the most exact method of determining fat in milk is to precipitate the fat, together with the casein, by means of a dilute acid, and to extract the precipitate with ether But in the case of the milks cited above, coagulation is incomplete and clear filtration not possible. The author accounts for this by the fact that normal cow's milk contains a large amount of soluble calcium salts (from 6 to 7·5 grammes per litre), chiefly phosphates, which largely assist the coagulation; whereas human milk only contains from 1·5 to 2·8 grammes per litre. In the case of humanized milk the cause is the same, as the phosphates are precipitated by the sterilization, and only partially redissolve on cooling. Similarly, condensed milk, when diluted, according to the directions, with four or five parts of water, contains only 3·5 to 4 grammes of mineral matter per litre. Experiments showed that the added sugar played no part in the imperfect coagulation, which was entirely due to the small proportion of salts.

On these facts the author has based the following process, which he has found rapid and exact, and applicable in every case. It consists in precipitating the casein and fat with a solution prepared by mixing about 70 grammes of freshly precipitated calcium phosphate with 12 c.c. of glacial acetic acid and about 250 c.c. of water, and making the solution up to 2 litres. In the determination 90 c.c. of this solution are mixed with 10 c.c. of the milk, the precipitate filtered off, dried, and extracted with ether in a Soxhlet apparatus. If required, the lactose may be determined in the filtrate in the usual way, after adding a few drops of potash to facilitate the precipitation of the cuprous oxide.

In the case of condensed milk, 10 grammes are diluted with warm water, the mixture cooled, made up to 100 c.c., and 10 c.c. taken for the estimation. C. A. M.

Action of Micro-organisms of Milk on Indigo-Carmine. L. Vaudin. (*Ann. de Chim. Analyt.*, vol. ii., pp. 441-445.)—From a series of experiments made on the decolorization of indigo-carmine by milk, the author agrees with Duclaux in

attributing this reaction to the influence of microbes, and not to the action of albuminoids. He suggests that the addition of alkalies and antiseptics to milk should be prohibited, and that the decolorization test should be applied to all milk offered for sale, the minimum permissible standard of time ensuing before decolorization occurs being fixed at twelve hours at temperatures below 15° C., eight hours at 15° to 20° C., or four hours above 20° C. C. S.

Estimation of Volatile Fatty Acids in Butter. E. Wrampelmeyer. (*Landw. Versuchsst.*, 1897, xlix., 215; through *Chem. Zeit. Rep.*, 1897, 269.)—In carrying out the Leffmann-Beam process (*cf.* ANALYST, xxi., 259), the author dissolves the butter soaps in 250 c.c. of well-boiled hot distilled water, adds one drop of indicator and 50 c.c. of sulphuric acid (strength not stated). The whole is then distilled in a current of superheated steam, which is introduced into the flask through a tube reaching below the level of the liquid; and the vapours are made to pass through a condenser at least 0·5 metre long. The steam is obtained from distilled water free from CO_2, and is superheated by means of a flat flame burner during its passage along a copper tube 30 cm. long and 1·4 cm. in diameter. By working in this manner, the amount of decinormal alkali required by 5 grammes of the butter-fat is increased some 5 or 6 c.c., and as the figures yielded by pure margarine remain the same as in Wollny's process, the delicacy of the test is thus raised 15 or 20 per cent. F. H. L.

On the Compulsory Addition of Sesame-Oil to Margarine. von Raumer. (*Zeit. angew. Chem.*, 1897, 749-751.)—By an imperial statute of July 4, 1897, it was made obligatory on all margarine manufacturers in Germany to add at least 10 per cent. of sesame-oil to their products, so that any subsequent admixture of the margarine with butter might be readily detected by Baudouin's reaction.

In the author's opinion, such an addition is absolutely useless, for, apart from the fact that the margarine and butter industries are frequently carried on by the same individuals, and that the greater part of the admixture of margarine with butter takes place in large factories, where obviously margarine containing sesame-oil would not be used for the purpose, it is pointed out that Baudouin's test cannot always be regarded as conclusive. Thus it was shown by Spampani and Daddi (*Staz. Sper. Agric. Ital.*, 1896, xxix.) that the fat from the milk of goats whose fodder had contained sesame-oil gave Baudouin's reaction.

Of various vegetable coloring matters examined by the author, only one—turmeric—gave the same colour as sesame-oil with hydrochloric acid and furfural. But although turmeric gave the pink colour with hydrochloric acid alone, it was not possible to subsequently test for sesame-oil by adding furfural. (*Cf.* ANALYST, this vol., p. 235.)

In the case of yellow and orange coal-tar colours, the following gave a pink coloration with hydrochloric acid alone: (1) Ponceau. (2) Orange II., β-naphthol orange, tropæolin 000 No. 2. (3) Acid yellow G, the sodium salt of amido-azo-benzene sulphonic acid. (4) Dimethyl aniline orange, the sodium salt of dimethyl-

amido-azo-benzene-mono-sulphonic acid. (5) Methanil yellow S, the sodium salt of a disulphonic acid of phenyl-amido-azobenzene.

In the case of the two first, it is suggested that the colour might have been due to impurities. Butter-fat colored with any of these gave exactly the same coloration with hydrochloric acid alone as that shown by sesame-oil with hydrochloric acid and furfural; and although the author has no knowledge that these are employed to colour butter, there is nothing to exclude their use, whilst it is possible that other coloring matters may behave in a similar manner. C. A. M.

Estimation of Glycerol in Wines. F. Bordas and S. de Raczkowski. (*Ann. de Chim. Analyt.*, vol. ii. [20], pp. 381-383.)—The first step is to separate the glycerol by distillation in a current of steam. This is effected by heating 25 c.c. of the wine—previously neutralized by potassium hydroxide—in a short-necked 300 c.c. flask immersed in a brine-bath, the temperature of which is gradually raised to 110° C. The removal of the alcohol and more volatile substances is facilitated by connecting the apparatus with an exhaust; and as soon as these are all distilled, a current of steam is passed through the liquid in the flask (still kept at 110° C.) during three hours, when the glycerol distils over. At the close of the operation the action of the exhaust is continued until the delivery-tube is thoroughly cooled down. The distillate containing the glycerol is then made up to 200 c.c. for titration. When the wine is poor in glycerol, 50 c.c. should be taken for the experiment, in which case the steam is passed for an extra half-hour. A condenser at the rear of the receivers prevents any increase of pressure in the distilling flask.

The glycerol is estimated colorimetrically: four test-tubes are taken, into each of these 5 c.c. of the before-mentioned solution are placed along with *exactly* 2·5 c.c. of pure concentrated sulphuric acid, and 0·5, 1, 1·5, and 2 c.c. of a solution of potassium bichromate (24 grammes per litre) added to them respectively. The contents of one of the tubes will, after boiling, exhibit a yellowish-green tinge, and this one is selected as the basis for a second series of tests wherein the quantities of bichromate added are graduated by one-tenth of 1 c.c. above and below the quantity employed for the tube in question. From this series is selected the tube immediately preceding that one in which the liquid is of a slightly yellowish-green tint; and since 1 c.c. of the bichromate equals 0·0025 of glycerol, the volume of bichromate employed, multiplied by five, gives the quantity of glycerol per litre of wine. In case of doubt between two tubes, the mean is taken, but such instances are hardly likely to occur.

In very sweet wines the complete extraction of the glycerol is prevented by the opposition of the syrupy residue to the penetration of the steam. C. S.

On the Microscopical Examination of Food Substances. A. Hebebrand (*Forsch. Ber.*, 1897, iv., 306, 307.)—The author has found a preliminary treatment of the substance (suspended in an alkaline solution) with chlorine to give the most satisfactory results, both as regards the clearness of the structure and the quantitative estimation of foreign substances. In his experience, the reagents usually employed, such as aqua regia and caustic soda, act too energetically in many instances,

and cause the proportion of foreign substance to be different from what it was in the original sample. Or if, on the other hand, weaker reagents are used, the structure does not appear with sufficient clearness.

A small quantity of the finely-powdered substance is mixed with 10 to 15 c.c. of a solution of 7 grammes of dry sodium carbonate in 100 c.c., and chlorine passed in for a few minutes (from two to ten, according to the nature of the substance), care being taken that the reaction remains alkaline. The liquid is then diluted with water, and the bleached material separated, washed twice with water, and examined.

This method is claimed to give especially good results with starches, and in some cases has enabled the author to make a correct quantitative determination of rye meal in the presence of wheat meal owing to the former being attacked by the chlorine much more rapidly than the latter. The results, however, cannot always be relied upon. C. A. M.

Copaiba Balsam and Gurjun Balsam. L. F. Kebler. (*Amer. Jour. Pharm.*, 1897, lxix., 577-579.)—The different products described in the U.S. Pharmacopœia as balsam copaiba, oil of copaiba, mass copaiba, and resin copaiba, are derived from shrubs and trees of the genus Copaiba, all of which, with the exception of two African species, are natives of tropical America. According to J. C. Umney, the substances obtained from the latter differ very much from the more common American products.

The author has examined a large number of commercial samples, with the object of obtaining data as to their composition. In every case his modification of the glacial acetic acid test (*Amer. Jour. Pharm.*, lxvii., 394) was found reliable for the detection of Gurjun balsam. The samples in the subjoined table marked 'copaiba' are said to be representative of the commercial article. Of the Para samples, all are good with the exception of that with a specific gravity of 0·9874 at 15° C., which in the author's opinion is not a normal Para copaiba, but a more concentrated oleo-resin. The solidifiable copaiba may also be taken to fairly represent those found in commerce. The author has never met with a sample with a specific gravity below 0·9800 at 15° C., which solidified well:

The demand for solidifiable copaiba, mass copaiba, and resin copaiba, is very limited, and the article most in use is a copaiba containing 40 to 60 per cent. of oil. In the U.S. Pharmacopœia only the solidifiable balsam copaiba (properly an oleo-resin of copaiba) is recognised, and the author considers that the official requirements for it are inadequate. Thus he states that the residue is not necessarily brittle in the absence of any fixed oil, that the range of specific gravity is too low, and that a better limit would be 0·9800–1·0173. The test for Gurjun balsam, by heating the substance to 130° C., is said to be erroneous, for none of the samples examined congealed at that temperature, but only became slightly more viscous. He considers that more stringent tests are required for resin copaiba, since at present almost any resin will answer the requirements. C. A. M.

Detection of Turmeric in Powdered Rhubarb. A. Jaworowsky. (*Pharm. Zeits. Russl.*, 1897, xxxvi., 543; through *Chem. Zeit. Rep.*, 1897, 281.)—One gramme of the sample is shaken for some minutes with 10 c.c. of chloroform, the liquid filtered, diluted with fifteen times its volume of petroleum spirit, and divided into two portions. One is shaken with 2 or 3 c.c. of sulphuric acid and the other with 1 or 1·5 c.c. of a saturated solution of borax. If the rhubarb is pure, the chloroform has a straw-yellow colour, which disappears on dilution. On addition of sulphuric acid, the acid becomes brown, and the rest of the liquid remains colorless. The borax causes no change. In presence of turmeric, the chloroform is yellowish-brown, and exhibits a green fluorescence. Petroleum spirit yields a flocculent yellow precipitate, but neither the colour nor the fluorescence of the chloroform is affected by it. The sulphuric acid itself is colored a magenta red, which quickly alters to a red and then yellow-brown; the other liquid turns violet. The borax solution becomes violet, but the spirituous layer is unchanged in its appearance.

F. H. L.

The Important Constituents of Taraxacum Root. L. E. Sayre. (*Amer. Jour. Pharm.*, 1897, lxix., 543-546.)—The most important constituents identified by the author in taraxacum root are: (1) a resin, soluble in chloroform and ether, and insoluble in alcohol; (2) a resin soluble in alcohol; (3) *taraxacerin*, a white, wax-like substance; (4) a bitter principle, *taraxacin*, which in concentrated solution is precipitated by many alkaloidal reagents.

Attempts to isolate the bitter principle in crystalline form all proved unsuccessful, for it was found impossible to obtain crystals free from oleo-resinous drops, though acetone appeared to be the most promising solvent.

Taraxacerin, the wax-like body referred to above, separates from alcoholic solution in cauliflower-like forms. It melts at about 45° C., and has an empirical formula corresponding to $C_9H_{15}O$, or a multiple of this.

The amount of ash in one sample of the root dried at 100° C., was 11·13 per cent. with the following composition:

	Per cent.
Silica	43·27
Alumina	18·07
Ferric oxide	0·80
Calcium oxide	5·75
Magnesium oxide	6·60
Potassium oxide	13·83
Sulphuric acid (SO_4)	4·22
Phosphorus pentoxide	trace
Carbon dioxide	6·53
Chlorine	1·20
	100·27

C. A. M.

ORGANIC ANALYSIS.

Examination of Wax. G. Buchner. (*Zeit. für öffent. Chemie*, iii., 570.)—In the *Chem. Revue über die Fett und Harzindustrie*, 1897, p. 261, K. Dietrich published some results obtained on examining bees-wax by Hübl's method and by Henriques' cold saponification method, leading to the conclusion that the constants obtained by Hübl's method are not always to be depended upon. The author has examined two samples of bees-wax, of unquestionable purity, by both methods, (*a*) by dissolving in 25 c.c. of warm petroleum benzine in the ordinary way, whereby some loss of benzine by evaporation is sustained, and (*b*) by dissolving under special precautions, to avoid such loss. The following results were obtained:

HÜBL'S METHOD.

	I.		II.	
	(*a*)	(*b*)	(*a*)	(*b*)
Acid number	18·37	18·50	17·23	17·76
Ether number	75·98	75·81	75·98	74·60
Saponification number	94·35	94·31	93·21	92·36
Ratio	4·15	4·10	4·41	4·20

HENRIQUES' COLD SAPONIFICATION METHOD.

Petroleum benzine boiling at 100° to 150° C.

	I.		II.	
	(*a*)	(*b*)	(*a*)	(*b*)
Acid number	19·48	19·48	19·11	19·11
Ether number	72·81	72·81	72·81	72·81
Saponification number	92·29	92·29	91·92	91·92
Ratio	3·74	3·74	3·90	3·90

Petroleum benzine boiling at 50° to 80° C.

	I.		II.	
	(*a*)	(*b*)	(*a*)	(*b*)
Acid number	18·39	19·48	17·64	19·11
Ether number	53·60	71·09	54·53	68·16
Saponification number	72·99	90·57	72·27	87·27
Ratio	2·91	3·65	3·09	3·56

The lower the boiling-point of the benzine, the more difficult is it to effect the solution of the wax, and the more incomplete is the saponification. For cold saponification, petroleum benzine boiling at 100° to 150° C. is indispensable; but the results obtained are very exact, surpassing those yielded by Hübl's method. Hübl's method has, however, the advantage of rapidity of execution. H. H. B. S.

Examination of Rose-Oil. F. Dietze. (Reprint from *Südd. Apoth. Zeit.*, 1897, No. 89; through *Chem. Zeit. Rep.*, 1897, 288.)—The author states that geranium-oil can be detected in rose-oil by determination of the saponification number, and he has obtained the following values for this constant in different specimens of the two substances: Rose-oil from Germany, 8·6; Bulgaria, 9·2; Turkey, 8·9; geranium-oil from France, 59·1; Africa, 53·1; Spain, 75·3; India, 32·5. He also suggests the annexed specification: Genuine rose-oil should have a specific gravity not exceeding 0·870 at 15°; its solidifying point should not be lower than 15° or 20°; its saponification number not higher than 9·5 or 10; and its rotatory power in a 100 mm. tube at 20° C. not more than −1° 30′. F. H. L.

Properties of Some Essential Oils. Reports of Schimmel and Co. and H. Haensel. (*Deutsche Chem. Zeit.*, 1897, xii., 385.)—Oil of Bay.—When freed from terpenes this oil separates into two immiscible layers; the upper one is yellow and has a sp. gr. of 0·9533; the lower is a brown commercial product, sp. gr. 1·0358; and the terpenes themselves have a sp. gr. of 0·8146 (all at 18° C.).

Oil of Aniseed.—This is liable to be adulterated with oil of fennel and stearoptene.

Oil of Cananga is largely sophisticated with cocoa-butter, which raises the saponification number; but as other esters (Ylang-ylang oil), boiling at a lower temperature, are apt to be present, this test alone is not satisfactory. Its behaviour with alcohol and in a freezing mixture are, however, characteristic:

	Sp. gr.	Rot. Power.	Sap. No.	Solubility in Vols. of 95 per cent. Spirit.	Behaviour in Freezing Mixture.
Pure Cananga, crude	0·916	−21° 27′	17·8	0·5 to 2.	Liquid.
,, ,, refined	0·915	−20° 48′	16·0	,,	,,
Mixed with cocoa-fat	0·919	−17° 1′	83·7	Sep. of oil.	Becomes buttery.
Ditto and rectified...	0·908	−21° 50′	14·4	0·5 to 2.	Liquid.

Oil of Cardamoms. (1) From *Malabar*.—Sp. gr., 0·943; rot. power, +34° 52′ at 19°; sol. in 4 parts of 70 per cent. alcohol; sap. no., 137 (? 13·7). Contains acetic acid, cineol, and dextro-terpineol. (2) From *Siam*.—Sp. gr., 0·905; r. p., +38° 4′ at 42°; sol. in 1·2 parts of 80 per cent. alcohol; sap. no., 18·8; after acetylation, 77·2 (= 22·5 per cent. of borneol). Contains + borneol and camphor. (3) From *Cameroons*.—Sp. gr., 0·907; r. p., −20° 34′; sol. in 7·8 parts of 80 per cent. alcohol. Contains cineole. (4) *Oil of Grains of Paradise*.—Sp. gr., 0·894; r. p., −3° 58′; sol. in 10·11 parts of 90 per cent. spirit.

Oil of Cedar-wood.—Cedrene, the hydrocarbon of this oil, after distillation over sodium, boils at 131°-132° at 10 mm. pressure; its r. p. is −47° 54′; and it is a

sesquiterpene. With chromic and glacial acetic acids it yields a ketone (cedrone), boiling at 147° to 151° (7·5 mm.). Its oxime boils at 175° to 180° (8 mm.), and forms an acetate boiling at 185° to 190° (9 mm.). By reduction with sodium in ethereal solution the ketone gives liquid isocedrol (b.p., 148° to 151° at 7 mm.), the benzoic ester of which boils at 221° to 223° C. at 6 mm.

OIL OF CITRON.—For this and the two next oils, the Italian Government has specified the following (far too severe) requirements: Sp. gr. at 15°, 0·857 to 0·862; r. p. at 20°, between +57° and +67° in a 100 mm. tube. When 50 c.c. are fractionated, the first 5 c.c. distilled must have an opticity not exceeding 5° less than the original oil. (According to Soldiani and Bertè, when half the oil is distilled the distillate should have a r. p. higher than that of the residue, and also than that of the sample.)

OIL OF ORANGE.—Sp. gr., 0·847 to 0·853 at 15°; r. p., +96° to 98° at 20°.

OIL OF BERGAMOT.—Sp. gr., between 0·882 and 0·886 at 15°; r. p., between +8° and +20° at 30°; the ester content, determined on 2 or 4 grammes of the oil with normal potash in a flask fitted with inverted condenser, not below 30 per cent.; 5 grammes evaporated on the water-bath not to leave more than 6 per cent. of residue; must be soluble in 0·5 vol. of 90 v/v* alcohol, and remain clear on further dilution.

AMERICAN FIR-OIL (*Pinus sylvestris*).—Sp. gr., 0·884; r. p., −24° 8′ at 18°; sol. in 8 or more parts of 90 per cent. spirit with slight turbidity; sap. no., 34·8 (the ester is probably bornylic acetate; if so, it equals 12·1 per cent.). The English oil is also lævorotatory, while the German and Swedish specimens are dextrorotatory.

HEMLOCK-OIL (*Abies Canadensis*).—Sp. gr., 0·911; r. p., −25° 22′ at 16°. Contains 38 per cent. of lævorotatory bornylic acetate, also lævorotatory pinene, and is sol. in 1 or more parts of 90 per cent. alcohol.

SPRUCE-OIL (*Picea nigra* or *alba L.*).—Sp. gr., 0·913; r. p., −23° 50′ at 81°; sol. in 0·5 vol. of 90 per cent. alcohol, and yields with 5 vols. a strongly opalescent liquid. It also contains lævorotatory bornylic acetate and lævorotatory pinene, and cannot be distinguished either by odour or otherwise from the previous oil.

GUAIACUM-OIL in its normal state melts at 45° or 50°; but for the preparation of essences a more fluid sort is preferred, which remains liquid at summer temperatures. The crystalline alcohol, guaiacol, is odourless. The oil forms a favourite perfume, and is used in soap.

OIL OF MYRRH.—Bisabol myrrh, coming from the interior of Somaliland, has been investigated by Tucholka. On shaking out the alcoholic resin solution with petroleum spirit, evaporating the solvent and distilling the residue with steam, a pale-yellow limpid oil was obtained, having a characteristic odour, the yield being 7·8 per cent. Dried over calcium chloride, its sp. gr. at 24° was 0·8836; it boiled between 220° and 270°; and its optical values were:

$$n_{D\,22\cdot3}^{\circ} = 1\cdot4874, \text{ and } [\alpha]_{D\,24}^{\circ} = -14^{\circ}\ 20' \text{ (100 mm. tube).}$$

By the action of HCl gas on its ethereal solution, 65 per cent. of a hydrochloride

* Per cent. by volume (*cf.* ANALYST, xxii., 89).

was produced, which, after repeated crystallizations from alcohol and ether, melted at 79·3°. Sodium acetate and glacial acetic acid split this up into a hydrocarbon with sp. gr., 0·8914 at 17°; b. p., 259° to 260·5°; and refractive index, 1·4608. It appears to be a new terpene, and has been named bisabolene.

Oil of Petit-grain.—Passy has lately found that this oil contains considerable quantities of geraniol, partly free and partly as the acetic ester; these seem to exert much influence on its odour.

Oil of Peppermint.—To estimate the menthol, 5 grammes are heated under an inverted condenser with (exactly) 5 c.c. of acetic anhydride for half an hour, and, after cooling, the excess is titrated with normal soda, the strength of the anhydride being determined in the meantime in a similar manner. The volume of alkali neutralized × 0·156 gives the menthol.

Oil of Rosemary has been proved to contain pinene. It should answer to the following requirements: sp. gr., above 0·9; r. p., +; sol. in 0·5 vol. of 90 per cent., and also in 10 vols. of 80 per cent. alcohol; on distillation, the first 10 per cent. must have a + r. p.

Oil of Sandal-wood should be examined by acetylation, determination of sp. gr., r. p., and sol. in 70 per cent. spirit. Colour reactions are useless.

Oil of Vetiver (*Cuscus*) differs largely in its constants. When pure it has sp. gr. 1·019 to 1·027 at 15°; r. p., +25° or 26°; sap. no., 70 to 80; sol. in 80 per cent. alcohol 1·5 to 2 vols.

Oil of Xanthorrhœa.—On distilling the resin from the Australian "yellow grass tree," 0·37 per cent. of yellow oil smelling like storax is obtained. Sp. gr., 0·937; r. p., −3° 14′; acid no., 4·9; sap. no., 74·3; ester no., 69·4. The free acid is cinnamic, and melts at 133°. On saponification, 20 per cent. of the same substance may be recovered.

Oil of Marvel of Peru (*Tanacetum balsamita L.*).—Prepared from the flowers; yield, 0·064 per cent.; odour like tansy; sp. gr., 0·943; r. p., −53° 48′ at 16°; sap. no., 21. Insol. in 80 per cent., but sol. in 1 or 2 vols. of 90 per cent. alcohol, further additions causing turbidity and separation of white flocks. Distils between 207° and 283°.

Heliotropin.—A product having this name has been put on the market by a Swiss firm. It consists of heliotropin, 90 per cent.; vanillin, 10 per cent.; solution of ionone, 0·5 per cent.; and a trace of rose-oil.

Ionone.—A crystalline preparation called "ionone" has been met with, composed of one of the artificial musks, which had been given a violet-like odour by being crystallized from ionone. It contained nitrogen in the form of a nitro compound, exploded on heating with sodium, while its odour changed from that of violets to that of musk on boiling with water.

Concrete Violet.—This is an American product belonging to the class of fixed scented oils. It consists of a mixture of fat, oil of iris (sweet flag) and artificial musk. The latter crystallizes out of its solution in petroleum ether. If the molten substance is shaken with 80 per cent. alcohol, the fat filtered off, and the solution treated with parabromphenylhydrazine, a yellow precipitate is produced, which

crystallizes in transparent scales from hot spirit (m. p., 156°). The odour is therefore due to irone, and not ionone.

Myristic acid is much used as the fat or solid matter in these fixed scented oils; and the following figures give approximately the amount of it contained in different varieties: Jasmine, 50 per cent.; elder flowers, 49 per cent.; acacia, 69 per cent.; fixed rose-oil, 73·8 per cent.; reseda (mignonette), 85 per cent.; violet flowers, 86 per cent.

[NOTE BY ABSTRACTOR.—This article also contains a number of further details respecting these oils, etc.; but they do not appear to possess any analytical interest.]

F. H. L.

Application of Maumené's Method to the Examination of Essential Oils. M. Duyk. (*Rev. de Chim. Analyt. Appl.*, vol. v., pp. 442-445.)—In order to prevent the violence of the reaction which ensues, in applying this test to essential oils, it was found necessary to dilute the oil with an inert substance, and for this purpose commercial, colorless, liquid paraffin was employed.

To apply the test, 4 c.c. of the liquid paraffin and 1 c.c. of essential oil are mixed by shaking in a 15 c.c. flask fitted with a thermometer, the bulb of which is immersed in the liquid. Two c.c. of pure monohydric sulphuric acid are then carefully pipetted down the side of the flask, and, after the thermometer has been read, are shaken up with the other contents, the resulting increase of temperature being read off as soon as the maximum is obtained. The difference gives the increase occurring under the conditions of the experiment.

The subjoined figures were obtained by the foregoing method, the initial temperature being 120° C., and the weight of the flask 30 grammes:

TERPENE HYDROCARBONS.

Cymene, $C_{10}H_{14}$, from turpentine essence, 4° C.
Pinene, $C_{10}H_{16}$, from turpentine essence, 36° C.
Limonene, $C_{10}H_{16}$, from citron essence, 26° C.
Carvene (Limonene), from caraway essence, 26° C.
Thymene, $C_{10}H_{16}$, from thyme essence, 13° C.
Cedrene, $C_{15}H_{24}$, from cedar essence, 15° C.

OXYGENATED COMPOUNDS.

Anisol, from anise essence, 22° C.
Thymol, from thyme essence, 7° C.
Safrol, from sassafras essence, 33° C.
Carvacrol, from thyme essence, 4·5° C.
Apiol camphor, from parsley essence, 32° C.
Eugenol, from clove essence, 27° C.
Geraniol, from geranium essence, 31·5° C.
Menthol, from mint essence, 9° C.
Linalool, from linaloe essence, 38° C.
Eucalyptol, from eucalyptus essence, 22° C.
Terpinol, from turpentine essence, 26° C.
Santalol, from santol essence, 33° C.

Citral, from lemon-grass essence, 40° C.
Anisic aldehyde, 14° C.
Benzaldehyde, from bitter almond essence, 9° C.
Menthone, 11° C.
Citronellol, from citronella essence, 33° C.
Carvol, from caraway essence, 30° C.

ESSENTIAL OILS.

Santal—*East Indian:* Samples from different makers ranged between 22·5° C. and 31° C. That prepared by the author gave 30° C. *West Indian:* 12°, 16°, 18° C., according to the maker.
Cedar: different makes, 16° to 18° C.
Copaiva: 24° C. Gurjum: 21° C.
Mint: Mitcham, 16° C.; Saxon, 13° C.; Crépue Japanese, 20° C.
Lavender: French, 37°, 36°, 34° C.; English, 33° C.
Spike lavender: 29·5° to 30° C.
Rose: Pure Turkish, 34·5° C.
Geranium: Turkish, 24° C.; freed from hydrocarbons, 25° C.
Citron: 25° to 26·5° C.; freed from hydrocarbons, 29° C.
Portugal orange: 37° C.; Neroli, 36·5° C.; Petitgrain, 33·5° C.

Preparation of Sugar Liquors for Polarimetry. J. Diamant. (*Chem. Zeit.*, 1897, xxi., 981.)—The author recommends the use of zinc-dust to remove the excess of lead from sugar solutions which have been decolorized by means of lead acetate. The precipitates settle quickly, the liquids are much clearer than before treatment with zinc, and the salts of the latter metal are without influence on the readings of the polarimeter. F. H. L.

Use of Alcohol for the Reduction of Cuprous Oxide in Sugar Determinations. G. Bruhns. (*Zeit. für. öffent. Chemie*, iii., 573.)—The cuprous oxide obtained in gravimetric sugar-determinations by Fehling's solution is reduced by means of alcohol, and the copper weighed in the metallic state. The procedure is as follows: The copper precipitate is filtered off and ignited in a platinum crucible. The crucible is then covered with a lid, having a hole in the centre and 1 c.c. of methyl alcohol added, a drop at a time, through the hole, the crucible being meanwhile maintained at a red-heat. The lamp is now turned out, and 1 c.c. of methyl alcohol run in at one time. The drops of alcohol at first added assume the spheroidal state, and consequently evaporate but slowly, so that the vapour has time to exercise its reducing action upon the oxide. The 1 c.c. added after the lamp has been turned out prevents, by its evaporation, the entry of air into the crucible, and thus protects the copper, while hot, from oxidation. The vapour of the alcohol is finally ignited,

and when it has burnt out, the crucible lid is removed and the crucible exposed to the air until no further odour of alcohol or formaldehyde is given off. It is allowed to remain five minutes in the balance-case, and is then weighed. The weight is quite constant, but, for the sake of control, the crucible can be heated again for a short time and re-weighed.

Ethyl alcohol of 99 per cent. can be substituted for methyl alcohol; but in this case a little carbon separates, which discolors the copper, though scarcely any increase in weight is perceptible. H. H. B. S.

Reactions of the Glucotannins of the Cinnamic Acid Series. H. Kunz-Krause. (*Chem. Zeit.*, 1897, xxi., 941.)—These bodies exhibit several reactions common to the whole group, among which the following are the most important. Dissolved in alcohol and treated with metallic sodium, they give a yellow precipitate, which is easily soluble in water. They form yellow lead-salts. They evolve hydrocyanic acid with Liebermann's reagent in the cold. They yield glucosazones on the addition of phenylhydrazine.

The best-known member of the series is caffetannic acid (glucosyldihydroxycinnamic acid), which is identical with matétannic acid. This substance readily absorbs water, alcohol, and ammonia. It combines with orthophenylenediamine; and its osazone melts at 180° C. With uranium acetate it yields a reddish-brown precipitate, but no carbon dioxide is given off when the products of the reaction are insolated. With chloral hydrate it forms a yellow, rather unstable compound. By itself, and in presence of acids, caffetannic acid is quite permanent; even on warming alone or with dilute acids it is not easily attacked; but on heating with strong hydrochloric acid it is converted into an amorphous, humus-like body. Bromine water splits up the molecule into a soluble sugar and a brown insoluble substance containing the halogen. The reaction, however, does not proceed smoothly, so that it is impossible to estimate caffetannic acid by determination of the sugar with Fehling's solution. Nevertheless, the decomposition proves that these glucotannins are true glucosides, a point about which there has previously been some uncertainty.

F. H. L.

Volumetric Estimation of Uric Acid. J. W. Tunnicliffe and O. Rosenheim. (*Centralbl. Physiol.*, 1897, xi., 434; through *Chem. Zeit. Rep.*, 1897, 280.)—This process depends on the fact that piperidine combines with uric acid in molecular proportions (4·25 grammes of base equal 8·4 grammes of acid) to form a soluble salt. A $\frac{N}{20}$ solution of the former is prepared by dissolving about 4·2 grammes of piperidine in 1 litre of water, standardizing it on hydrochloric acid of equivalent strength, phenolphthalein being used as indicator. The sample of uric acid is suspended in water, heated nearly to the boiling-point, and the reagent run in; neutrality being shown either by the liquid becoming clear or by the use of phenolphthalein as before. Although the solubility of the urate at 15° is 5·3 per cent., it is better to employ hot solutions; and there is no danger of losing any piperidine by volatilization, as the reaction is instantaneous. The method is particularly adapted for the examination of urine; and the uric acid is best obtained in a form suitable

for titration by Hopkin's process. This consists in separating the acid as its acid ammonium salt, and then decomposing the latter with HCl. The crystals must, of course, be washed on a filter till free from hydrochloric acid; but 15 or 20 c.c. of water are usually sufficient for the purpose. The paper is then perforated, and the uric acid is rinsed into a flask with 20 or 30 c.c. of hot water. F. H. L.

INORGANIC ANALYSIS.

The Determination of Lead in Lead Ores. R. K. Meade. (*Jour. Amer. Chem. Soc.*, 1897, xix., 374-377.)—The following is recommended as a simple and rapid method for the determination of lead in galena and lead ores in general in the absence of barium, strontium, and calcium, and of metals oxidized to insoluble compounds by nitric acid: One gramme of the ore, or more if poor, is heated in a covered platinum dish on a sand-bath with 40 to 50 c.c. of a mixture of one part of sulphuric acid (specific gravity 1·84) and three parts of nitric acid (specific gravity 1·42) until the action has apparently ceased. 10 to 15 c.c. of hydrofluoric acid are then added, and the solution evaporated until fumes of sulphuric acid begin to come off. The dish is cooled, and after dilution of the liquid to about 100 c.c., the insoluble matter is filtered off, washed first with a 2 per cent. solution of sulphuric acid and then with alcohol, dried, ignited apart from the filter-paper, and weighed as lead sulphate.

Experiments with a solution of lead nitrate proved that no lead was lost by volatilization as fluoride, although the results were slightly lower on evaporating 25 c.c. of the solution with sulphuric and hydrofluoric acids than with sulphuric acid alone, the averages of six determinations being 0·4280 gramme and 0·4297 gramme respectively. 25 c.c. of the solution, to which 0·2 gramme of silica had been added, when evaporated with the two acids, gave 0·4285 gramme of lead sulphate.

The analysis of different lead ores by the method given by Fresenius (*Quant. Anal.*, 213), and by this method, after calcium, barium, and strontium had been proved to be absent, gave the following results:

	Fresenius. Per cent. lead.	New Method. Per cent. lead.
Galenite	77·34	77·46
Pyromorphite	75·26	75·35
Cerussite	76·46	76·53

Barium and strontium are rarely found associated with lead, and calcium, when present as calcite, may be removed by treating the ore with hydrochloric acid and filtering. The residue containing the lead is then treated with sulphuric, nitric, and hydrofluoric acids, as described above. C. A. M.

Note on the Analysis of Bronze and Brass. F. Fatet. (*Ann. de Chim. Analyt.*, vol. ii. [20], pp. 383-385.)—Having found that the titration of zinc in an ammoniacal solution containing copper cannot be accurately performed by means of sodium sulphide after the copper has been decolorized by potassium cyanide, and also that the presence of zinc falsifies the titration of the copper by the last-named reagent, the author examined the method proposed by F. Jean for estimating these

metals in impure galena—viz., titration of the two metals by sodium sulphide in an ammoniacal solution, then acidifying with hydrochloric acid, to redissolve the zinc, and, after boiling the filtered liquid and adding ammonia, titrating the latter metal with the same reagent, the copper being estimated from the difference between the two tests. He finds that this method affords an accurate and speedy means for the analysis of bronze and brass.

To check the end point of the precipitation of the sulphides, he recommends the test proposed by Mohr—*i.e.*, the brown arc formed at the point of contact between a drop of an alkaline solution of lead and a drop of the test liquid placed on filter-paper. C. S.

Estimation of Iron with Permanganate in Presence of Hydrochloric Acid. M. Hauffe. (*Chem. Zeit.*, 1897, xxi., 894.)—The author employs the following combination of well-known methods: *Reagents necessary.*—(1) Permanganate solution containing 3 grammes per litre, standardized on pure iron under the conditions as detailed below; (2) 100 grammes of crystallized manganese sulphate, dissolved in 1,300 c.c. of water and 200 c.c. of pure concentrated sulphuric acid; (3) a cold-saturated solution of mercuric chloride; (4) a dilute solution of stannous chloride. *Process.*—A sufficient quantity of the material under examination to serve for several titrations is dissolved in a moderate excess of warm HCl, and, if organic matter is present, the liquid is treated three times with some strong permanganate, and boiled till free from chlorine, any oxide of manganese thrown out being taken up in a few drops of acid. When cold, it is diluted to a definite volume, and an aliquot portion (50 to 200 c.c.) is heated to boiling in a beaker capable of holding 2 litres. Stannous chloride is then run in from a burette till, after all the iron is reduced to the ferrous state, enough of the reagent still remains unoxidized to give a slight precipitate when 100 c.c. of the mercuric chloride solution are next added (*cf.* the somewhat similar process, ANALYST, xxii., 299). If the excess of stannous chloride is too large, the precipitate of mercurous chloride becomes so bulky as to hide the pink colour in the final titration, but if the mercuric chloride does not produce any precipitate, too little tin has been employed. Finally, 60 to 100 c.c. of the manganese sulphate are introduced, the liquid cooled as rapidly as possible, 1 litre of water added, and the whole titrated with the permanganate. When only trifling amounts of iron have to be determined, a blank experiment should be carried out on 10 c.c. of the stannous chloride, 10 c.c. of HCl, and 50 c.c. of water, warmed together, and treated with $HgCl_2$, etc., as above, in order to make proper allowance for the few drops of permanganate required to yield a visible pink in such a large mass of fluid (1·5 litres).

Iron ores should be dried at 105°C., and 5 grammes dissolved, first by boiling with HCl (specific gravity 1·19), and then by fusion with alkali carbonates in the ordinary manner; and if the proportion of silica is not so high as to cause the liquids to boil badly, it need not be removed. The volumes employed should be adjusted to allow either 0·5 or 1·0 gramme of the mineral to be titrated according to its richness in iron. In the case of phosphates, 25 grammes should be dissolved in 50 or 60 c.c. of strong acid, and 5 grammes taken for each analysis; but the amount of manganese

sulphate should be increased to 100 or 150 c.c., so that there may be no odour of chlorine perceptible during the addition of the permanganate. F. H. L.

Estimation of Alumina and Iron in Phosphates. F. Jean. (*Ann. de Chim. Analyt.*, vol. ii. [20], p. 403.)—The solution of the phosphate is made up to 100 c.c., and, after the phosphoric acid has been thrown down by the ordinary citro-magnesia method, 50 c.c. of the clear liquid are pipetted into a bulb flask, and there concentrated to 8 or 10 c.c. This quantity is boiled with 25 c.c. of 66 per cent. sulphuric acid and 5 c.c. of fuming nitric acid until colorless, the elimination of the organic matter being accelerated by the addition, at intervals, of a few crystals of sodium nitrate or a little nitric acid. When cooled, the liquid is diluted and treated with alcohol to precipitate calcium sulphate. After filtration the alcohol is boiled off; and, after the addition of a few crystals of potassium chlorate, the iron and alumina are thrown down by ammonia.

When manganese is present, the precipitate is fused in a platinum crucible with an alkali carbonate and potassium nitrate, the mass being taken up with water and the residue (iron oxide) weighed. Manganese is determined by titration, and the alumina estimated by difference. C. S.

The Behaviour of Thoria with Oxalic Acid and Ammonium Oxalate, and the Estimation of Thoria. C. Glaser. (*Zeit. anal. Chem.*, 1897, xxxvi., 213-219.)—In a former communication (*Chem. Zeit.*, lxiii., 612; ANALYST, xxi., 274-277) the author stated that the thoria recovered after the ammonium acetate treatment, when redissolved, could no longer be completely precipitated by adding ammonium oxalate, boiling, and allowing the liquid to cool. This he now finds to be due to the fact that thorium oxalate in nearly neutral solution is soluble in a large excess of ammonium oxalate, a statement which confirms the results of other observers. When there is not an excess of ammonium oxalate, no precipitation occurs in a boiling nearly neutral mineral acid solution of thoria, but on cooling the thorium oxalate comes down in crystalline form. Ammonium acetate only increases the solvent action of the liquid. By adding oxalic acid, or by making the solution strongly acid with hydrochloric acid, the thorium is precipitated quantitatively even when there is a large excess of ammonium oxalate.

The composition of the precipitate varies considerably, according to the method by which it is obtained. Thus, on adding oxalic acid to a solution of thoria before boiling, a precipitate of the normal oxalate is formed on cooling; but if the solution be boiled before the oxalic acid is added, the precipitate consists of a mixture of thorium oxide and oxalate, the oxide being sometimes partially precipitated before the oxalic acid is added.

On precipitating thorium by ammonium oxalate (not in excess) from a nearly neutral solution, the normal oxalate is not obtained, nor is it when the thorium is precipitated by ammonium oxalate from a solution made strongly acid with hydrochloric acid.

From these experiments it follows that a complete separation of thoria and

zirconia by means of ammonium oxalate is only possible when care is taken to avoid a greater excess of ammonium oxalate than is required for the solution of the zirconium oxalate, but when cerium is also present, it is very difficult to avoid an excess on account of the insolubility of cerium oxalate.

The author finds further that in separating cerium and thorium oxalates by means of ammonium acetate, a large excess of the latter must be avoided, since cerium oxalate is slightly soluble in ammonium acetate. Only a few c.c. of the reagent are required to dissolve out the whole of the thorium from the mixed oxalates.

As it was possible that these facts might make an alteration necessary in the scheme of analysis given in the previous paper, a sample of monazite sand was analysed by that method, but it was found that, notwithstanding its solubility in excess of ammonium oxalate, the whole of the thoria had separated out completely.

It is, however, advisable to examine the filtrate from the mixed oxalates of thorium and cerium, by adding ammonia in excess, filtering, dissolving the precipitate in hydrochloric acid in excess, adding oxalic acid, and leaving the liquid in a warm place.

When a determination of cerium is not required, the solution of the earths in sulphuric acid can be treated at once with an excess of hydrochloric acid and oxalic acid, and the precipitated thorium and cerium oxalates separated in the usual way by means of ammonium acetate.

The following remarks refer to the table of the more important reactions of the rare earths in the former paper:

1. The statement that thoria and ceria are precipitated by ammonium carbonate as well as by ammonia (Graham-Otto, part 2, 902-904) is incorrect.

2. Ammonium oxalate precipitates thoria in cold, but not in boiling, solution. An excess of hydrochloric acid precipitates the oxalate quantitatively on cooling.

3. The statement that thorium oxalate kept in solution by means of ammonium acetate and ammonium oxalate is partially precipitated by hydrochloric acid should read: that in the presence of a sufficient excess of hydrochloric acid the precipitation is complete.

4. Mention should be made of the solubility of zirconium oxalate in hydrochloric acid.

5. Cerium oxalate is slightly soluble in ammonium acetate. C. A. M.

Analysis of Sodium Bicarbonate. G. Lunge. (*Zeit. angew. Chem.*, 1897, 169-171).—This method, which was devised by Sundstrom, depends on the fact that a solution of sodium bicarbonate, when treated with sodium hydrate, is converted into carbonate. The end of the reaction is indicated by the excess of sodium hydrate giving a brown colour with silver nitrate solution, used as an outside indicator. From the result thus obtained, together with that of the total acidity determined by titration with normal acid, the composition of the sample can be calculated.

The solution of sodium hydrate is prepared by dissolving commercially pure caustic soda in water till the specific gravity reaches 1·16, precipitating with barium chloride, adding barium hydrate to saturation and diluting the solution to normal strength.

The use of ordinary normal sodium hydrate did not give satisfactory results, and, as the author points out, the barium hydrate in Sundstrom's solution at once detects the presence of any carbonate. C. A. M.

Analysis of Commercial Liquid Ammonia. A Lange and J. Hertz. (*Zeit. angew. Chem.*, 1897, 224-228.)—The authors find that the residue left on the evaporation of German liquid ammonia consists chiefly of water, pyridine bases, acetonitrile, ethyl alcohol, and a little machine oil; with ammonium carbonate, benzene, and naphthalene as occasional impurities.

For the valuation of liquid ammonia in practice, it is sufficient to determine the amount of residue without taking into account its composition. This is done by placing the bottle in a horizontal position, and screwing on to the valves an open steel tube. By opening the valve, from 20 to 50 grammes are allowed to flow into a previously-weighed Erlenmeyer flask, and rapidly weighed after the insertion of the stopper. This has two openings, through one of which passes a glass tube (*a*), bent at right angles, whilst the other communicates with a potash tube (*b*). The glass tube is kept closed, so that the evaporating ammonia must pass through the potash tube. The evaporation, which is complete in from two to three hours, may be assisted by an occasional shake. The residue which it still contains is warmed to (at most) 40° C., and a current of dried air passed into the flask through the glass tube (*a*) Both tubes are then closed, the apparatus again weighed, and the amount of residue calculated.

It was proved by experiments that the different samples taken were homogeneous in character, and that none of the impurities referred to were lost during the evaporation of the ammonia. Thus, on taking samples of 33 grammes each from the same bottle in one-quarter, in one, and in five minutes, the amount of residue obtained was 0·9, 0·9, and 1·0 per cent. respectively.

The apparatus used by the authors for the volumetric determination of the residue consists of a glass tube of from 30 to 40 mm. internal diameter, which is fused at the bottom to a narrow tube of about 5 mm. diameter, this part holding at least 1·1 c.c. The larger part of the tube contains about 100 c.c., and has a mark at 49 c.c. corresponding to 33·3 grammes of ammonia. The lower narrow portion of 1·1 c.c. is graduated into fifteen parts, so that each corresponds to 0·2 per cent. The tube is filled to the mark with ammonia, a grooved cork inserted, and the liquid allowed to evaporate spontaneously. This takes about three hours, but the operation may be completed in half an hour by placing the tube in water. The presence of much water in the residue is a source of error, since the latter may then retain about 25 per cent. of ammonia, but with the average constituents of the residue the error is trifling. C. A. M.

Separation of Bromine from a Mixture of Soluble Bromides and Chlorides. Baubigny and Rivals. (*Comptes Rendus*, October 11, 1897, p. 527; through *Ann. de Chim. Analyt.*, vol. ii. [22], p. 425).—The mixture is treated with copper sulphate and potassium permanganate, a current of air being passed through the liquid to remove

the bromine, which is absorbed by a 3 to 4 per cent. solution of soda contained in a tube fitted with glass balls, which are kept apart by constrictions in the tube.

The mixed salts and the copper sulphate are placed in a long-necked flask containing water, and after solution has been effected by the aid of heat and the liquid has cooled down, the permanganate is added, the flask is connected with the air-supply and the absorption-tube, and is heated on the water-bath. To prevent loss by evaporation, the air is saturated with moisture by being passed through water in a flask on the same water-bath.

When all the bromine is driven over, the cold alkaline liquid in the condenser-tube is decanted and treated with a little gaseous sulphur dioxide, followed by a 10 per cent. solution of silver nitrate and a fairly large amount of nitric acid. In the acid liquid the sulphurous acid reduces any oxygenated bromine products present, and if heat be then applied, the nitric acid oxidizes the residual sulphur dioxide and the silver sulphite formed, leaving only silver bromide behind as the insoluble residue.

The silver nitrate should be added along with, and not *after*, the nitric acid, to prevent loss of bromine. C. S.

The Detection of Traces of Bromine by means of Fluorescein. H Baubigny. (*Compt. Rend.*, 1897, cxxv., 654-657.)—The method here described is based on the fact that bromine converts fluorescein into its tetra-bromo derivative, eosin. Test-paper is prepared by steeping paper in a solution of pure fluorescein (40 to 50 per cent.) in acetic acid and allowing it to dry. When moistened and brought into contact with bromine, such paper assumes a rose coloration. To detect bromides (in the absence of chlorides) the bromine is liberated by warming the solution with copper sulphate 16 grammes, and potassium permanganate 0·7 gramme, in 100 c.c., and passing a slow current of air through the flask while the test-paper is applied to the delivery tube. The formation of eosin on the paper after a few minutes shows the presence of bromine. The test is not suitable for the detection of bromine in the presence of free chlorine, especially if the latter be present in large excess, since chlorine gives a white derivative with fluorescein which masks the effect of the bromine. In such cases the free halogens may be converted into chloride and bromide, and then tested by treating the solution with copper sulphate and permanganate without warming and passing air through the flask. When chlorine is present alone, the paper remains unchanged after ten minutes; but if as little as 0·001 gramme of bromide be present with 5 to 10 grammes of a chloride, rose-coloured streaks appear within four or five minutes. The presence of an iodide does not interfere with the test if it is first transformed into iodate by warming the solution with a little permanganate, for iodine is not then liberated on the subsequent addition of the copper sulphate. The author is still studying the method of proceeding in the case of insoluble bromides. The test-paper is said to keep as well as turmeric-paper. C. A. M.

On the Estimation of Sulphuric Acid as Ammonium Sulphate. F. Marboutin and A. Pecoul. (*Bull. Soc. Chim.*, 1897, xvii., 880, 881.)—Weinig described a method

for determining sulphuric acid in dilute solutions by adding an excess of ammonia, evaporating and drying the ammonium sulphate at 115°. Shiver (*Chem. Soc.*, 1895, 351) found that the results thus obtained were too low, and recommended the addition to the residue of a little strong ammonia, evaporation on the water-bath and drying at 120° C. The authors tested this modification on $\frac{N}{20}$ solutions, but their results were still too low. In order to determine under what conditions this source of error might be avoided, they evaporated 100 c.c. of the solution (yielding theoretically 343·6 milligrammes of ammonium sulphate) with an excess of ammonia at 65°, and brought the residue gradually up to 120°, with the following results :

	Milligrammes.
At 65° after forty-eight hours (the time required for evaporation)	343·5
The residue heated at 70° for twenty hours	343·5
75° „ „	343·7
80°	343·6
85°	344·2
90°	345·4
95°	346·2
100°	345·2
110°	344·8
120°	343·3

The authors attribute the increase of weight which takes place at 85° to the liberation of free sulphuric acid which absorbs moisture from the atmosphere.

C. A. M.

Note on the Separation of Silicic and Tungstic Acids. J. S. de Benneville. (*Jour. Amer. Chem. Soc.*, 1897, xix., 377-379.)—A common method of determining silicon in tungsten steel and ferro-tungsten is to dissolve the tungstic oxide on the filter by means of hot dilute ammonia, and so obtain the silica at once for determination. It has been pointed out by various chemists that precipitated silicic acid, and even amorphous silica, are perceptibly soluble in hot ammonia, and the author finds that this is also the case with cold ammonia. He therefore advocates the method, recommended by Arnold, of weighing the total oxides and volatilizing the silica with hydrofluoric acid, with the addition of a few drops of sulphuric acid, as the most satisfactory.

A sample of wolframite, containing 65·5 per cent. of tungsten trioxide, and by the volatilization method 5·61 per cent. of silica, gave, on dissolving the tungsten oxide from the silica by ammonia : (1) Insoluble silica, 3·84 per cent., and soluble silica, 1·64 per cent. ; and (2) insoluble silica, 3·22 per cent., and soluble silica, 2·20 per cent. The silica was mainly derived from intermixed mica. C. A. M.

The Determination of Silica in Blast Furnace Slag. G. H. Meeker. (*Jour. Amer. Chem. Soc.*, 1897, xix., 370-374.)—For the method here described there is claimed (1) greater accuracy than in the usual methods on account of more complete dehydration of silicic acid and thorough decomposition of the slag, and (2) greater rapidity and ease of execution.

Half a gramme of the finely-powdered slag is mixed in a basin with about 3 c.c.

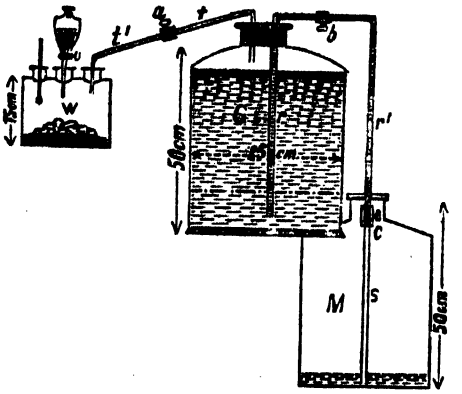
of water, and then stirred up with 10 c.c. of concentrated hydrochloric acid, till the slag has dissolved as completely as possible. 40 c.c. of sulphuric acid (1 : 4) are then poured into the basin covered with an inverted funnel, and the liquid boiled until fumes of sulphur trioxide appear. After cooling, 10 c.c. of hydrochloric acid are added, the liquid diluted and boiled for one minute, the basin being covered with a watch-glass. The residue is then filtered off, washed five times with hot hydrochloric acid (specific gravity 1·10) and five times with hot water, ignited, and weighed. The silica is remarkably pure. In "chilled" slags the impurities amount to from 0·05 to 0·20 per cent.

This method has been compared with a method consisting of two evaporations to dryness with hydrochloric acid, the heat being regulated so as not to exceed 120° C., and finally purifying the silica with hydrofluoric acid, and has, as a rule, given results in close agreement, though somewhat lower (about 0·1 per cent.), owing to the more complete dehydration of the silicic acid. The only exceptions to such agreement were in cases such as slags associated with spinel, in which the treatment with hydrofluoric and sulphuric acids changed the impurities (*e.g.*, alkalies) in the spinel into other compounds, which would influence the final result.

The percentage of silica obtained by the ordinary method and by this method in a slag containing spinel residue were:

	Ordinary Method.	New Method.
Silica and impurities	35·42 ...	31·20
Impurities determined by treatment with hydrofluoric and sulphuric acids ...	5·88 ...	0·20
	29·54	31·00

Attempts to readily determine alumina and lime in the filtrate from the silica all failed, the results being much too low. C. A. M.



On the Estimation of Phosphoric Acid as Phosphomolybdic Anhydride. H. Pellet. (*Rev. Chim. Analyt. Appl.*, vol. v. [20], p. 405.)—The double precipitation indicated by Woy (ANALYST, xxii., 250) for obtaining a pure precipitate of ammonium phosphomolybdate is considered unnecessary. It is found that when a sufficiency of ammonium nitrate is used, the molybdic acid is not precipitated, and the dried precipitate of ammonium phosphomolybdate corresponds to 3·75 grammes of phosphoric acid or to 3·95 of phosphomolybdic acid.

The estimation can therefore be accelerated by substituting ignition for desiccation, provided the heat is applied slowly and the heating is not continued too long, otherwise the results may be too low. C. S.

Valuation of Calcium Carbide by Measurement of the Acetylene it evolves. F. Fuchs and F. Schiff. (*Chem. Zeit.*, 1897, xxi., 875.)—When olive-oil is shaken for half an hour with acetylene, it dissolves 48 per cent. by volume of the gas; but if a layer of the oil previously saturated and 15 mm. thick is floated on the surface of water contained in the holder of the apparatus described below, the further loss

of acetylene in the time taken by each experiment does not exceed 1·5 or 2·0 per cent.

The generator, as seen in the accompanying cut, consists of a three-necked Woulffe's bottle (*W*), carrying a thermometer, a stoppered funnel, and a leading tube for the gas, the bottom of the vessel being covered with asbestos to avoid danger of breakage by the heat produced during the decomposition of the carbide. The gas-holder (*G*) is a glass bottle 50 cm. high and 25 cm. in diameter, having a capacity of 15 litres, and filled with water bearing the film of oil already referred to. The inlet tube is cut off just below the cork, so that the gas does not come in contact with the water itself. The outlet for the displaced liquid is a tube passing through the same cork, reaching to the bottom of the vessel, bent twice at right angles, and having both legs of equal length. At its external extremity it is connected by means of a short piece of rubber tube provided with a screw clip to another length of glass tube, passing to the bottom of a second vessel (*M*) the same size and shape as *G*, which at the beginning of the test contains exactly 1 litre of water, and stands at a lower level. By this arrangement, when the tube between *G* and *M* is full of water, it acts as a syphon, so that the gas in *G* and also in the generator is under diminished pressure, and there is no danger that the water in the funnel of the latter will be blown out when the cock is opened.

About 30 grammes of carbide are taken for analysis, and 200 c.c. of water are used to decompose it, the rate of admission through the funnel being regulated with the stop-cock. Although the introduction of the water alters the capacity of the apparatus, if the generator is well shaken after the production of gas has ceased no error will arise, because water dissolves exactly its own volume of acetylene. In about an hour and a half the temperature of the generator will have fallen to its original point. The generator *W* is well shaken, the clamp at *c* is then closed, *M* and the glass tube *s* removed, and *r'* is brought below the surface of a known quantity of water contained in a tall beaker. The clamp is again opened, and as the liquid runs back into *G*, a measured amount of water is poured into the beaker till the level is the same in both vessels, when *G* and the generator are evidently once more under ordinary atmospheric pressure.

The volume of water which has been drawn back into *G* out of the beaker, deducted from that which has passed from *G* into *M* during the decomposition of the carbide, thus gives the volume of acetylene generated; and this is corrected for temperature, pressure, and vapour tension of water in the usual way.

Two samples of Neuhausen carbide gave as the mean of five tests each 286·8 and 297·6 litres per kilogramme (4·59 and 4·88 cubic feet per lb.). F. H. L.

The Analysis of Commercial Calcium Carbide and Acetylene. G. Lunge and E. Cedercreutz. (*Zeit. angew. Chem.*, 1897, 651-655.)—The gas produced on adding water to commercial calcium carbide is never pure acetylene, but contains impurities up to 4 per cent., including sulphuretted hydrogen, phosphuretted hydrogen, ammonia, carbonic oxide, hydrogen, nitrogen and oxygen. Of these the most important are the two first. In good calcium carbide the amount of calcium phosphide and calcium sulphide is very trifling; but the authors have met with a sample containing so much of the former that the gas liberated ignited spontaneously.

In the analysis a sample of from 50 to 100 grammes, as representative of the bulk as possible, is decomposed with water, and the gas conducted into a laboratory gasometer holding not less than 40 litres, and the water in which is saturated with acetylene. Here it is measured and reduced to standard temperature and pressure. Theoretically, 100 grammes of pure calcium carbide yield 40·625 grammes of acetylene (= 34·877 litres), and commercial carbide ought to produce not less than 300 litres of gas per kilo.

For the determination of the phosphuretted hydrogen the ordinary method of oxidation with bromine water is not applicable, on account of the strong action of bromine on acetylene, and the authors therefore employ a solution of sodium hypochlorite as the oxidizing agent. From 50 to 70 grammes of the carbide in lumps are decomposed by water, which is allowed to fall drop by drop from a stoppered funnel passing through the cork of the flask. The outlet tube of the flask is connected with a tube composed of a series of bulbs, in which are placed 75 c.c. of a 2 to 3 per cent. solution of sodium hypochlorite. After the whole of the carbide has been decomposed, which takes from three to four hours, the flask is filled to the neck with water, a little air drawn through the apparatus, the contents of the bulb-tube emptied into a beaker, and the phosphoric acid determined by precipitation with magnesia mixture.

The sulphur, which has been simultaneously oxidized, can be determined in the filtrate from the ammonium magnesium phosphate precipitate by acidifying with hydrochloric acid and precipitating with barium chloride. C. A. M.

The Commercial Analysis of Sulphur Chloride. G. A. Le Roy. (*Rev. de Chim. Indust.*, 1897, viii., 294, 295.)—The chief industrial uses of sulphur chloride are in the vulcanizing of rubber, the preparation of artificial indiarubber, and the treatment of minerals containing gold. It contains normally 47 per cent. of sulphur and 53 per cent. of chlorine, but in many industrial samples the proportions are very different from this. Thus, in several the author found as much as 10 per cent. of uncombined sulphur in solution, whilst in others there was a large excess of free chlorine.

In Rose's method of analysis the sulphur is estimated by oxidation with fuming nitric acid and precipitation as sulphate, and the chlorine determined by difference. In place of this, the author describes the following volumetric method: From 10 to 12 grammes of the sample (roughly measured) are placed in a graduated flask

containing a known weight of crystallizable benzene; the flask and its contents are weighed after the addition, and the difference gives the amount of sulphur chloride taken. The liquid is made up to the mark with benzene, and an aliquot portion used in the determination.

The fraction taken is shaken with a known volume of standard soda, containing 19·37 grammes Na_2O per litre (1 c.c. = 0·01 gramme sulphur), which decomposes it into the sulphide, sulphite, hyposulphite, sulphate and chloride of sodium, with the liberation of some sulphur in the free state. The flask is then warmed on a sand-bath, which causes the benzene to evaporate and the sulphur to dissolve in the soda. When the sulphur has completely dissolved, an excess of hydrogen peroxide is added. The latter must be neutral and free from substances which can be precipitated by silver nitrate. On warming the liquid, the various compounds of sodium and sulphur are converted into sulphate. The excess of hydrogen peroxide is removed by boiling, or, if necessary, by the addition of several drops of permanganate solution, and after cooling the excess of soda is titrated with normal nitric or sulphuric acid. The quantity of soda left free, plus the soda in combination with the chlorine subsequently determined, deducted from the total amount of soda taken, gives the number of c.c. equivalent to the soda converted into sulphate. From this the amount of sulphur is obtained by multiplying by 0·01.

In the liquid thus neutralized, the chlorine is determined by titration with a silver solution by Mohr or Volhard's method. C. A. M.

Use of Caustic Alkalies in a Powdered Condition. A. Seyda. (*Zeit. für öffent. Chemie*, iii., 438.)—Powdered caustic alkali is recommended for use in the preparation of alcoholic saponifying solutions, etc. The quantity required is weighed approximately in the form of stick caustic, and is then finely powdered and dried in an exsiccator over sulphuric acid. Alkali in this powdered condition dissolves almost immediately in alcohol. The author uses powdered sodium hydrate prepared in this way in his method of testing organic preparations for iodine (ANALYST, vol. xxii., p. 325), and suggests its use for many other purposes where fusion with soda is required. H. H. B. S.

APPARATUS

A Combustion Boat with Partitions. E. Murmann. (*Zeit. anal. Chem.*, 1897, xxxvi., 380-381.)—In the ordinary boat the melted substance collects in the cooler end where the entire mass is suddenly decomposed when the decomposition temperature is reached. This is obviated by the use of a partitioned boat, in which only a small portion of the substance is decomposed at a time. The boats are made of porcelain, with ten divisions, and may be obtained in two sizes (70 mm. by 10 mm. and 100 mm. by 13 mm.) from Lenoir and Forster, Chem. Phys. Institut. Vienna.

C. A. M.

THE ANALYST.

FEBRUARY, 1898.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE ANNUAL DINNER OF THE SOCIETY OF PUBLIC ANALYSTS.

THIS, the full report of which will appear in our next issue, took place at the Criterion on Tuesday, the 18th ult., the President (Dr. Bernard Dyer) occupying the chair. The Annual Meeting was held on February 2nd.

REPORT OF THE COUNCIL OF THE SOCIETY OF PUBLIC ANALYSTS ON THE SALE OF FOOD AND DRUGS BILL,

INTRODUCED IN THE HOUSE OF COMMONS IN 1897

BY THE

RIGHT HON. W. H. CHAPLIN, M.P., AND MR. T. W. RUSSELL, M.P.

THE Council of the Society of Public Analysts has considered the Sale of Food and Drugs Bill, introduced by the President and Parliamentary Secretary of the Local Government Board towards the close of the last Session, and desires to express its regret that the measure deals with so few of the recommendations of the Select Committee. It is to be remembered that the Select Committee of the House of Commons on Food Products Adulteration, which was appointed in 1894, sat for three Sessions, and collected a very large mass of evidence, from widely different sources, bearing upon the matters which it was appointed to consider. The outcome of its labours was a report, presented to Parliament in July, 1896, very fully summarising the evidence which had been collected, and concluding with an epitome, under twenty-three headings, of the directions in which, in the opinion of the Select Committee, the existing Food and Drugs Acts should be amended. It was confidently expected on all hands that the Government would introduce into Parliament a Bill giving effect to these recommendations, or at all events to the majority of them ; but the Bill produced at the close of the last Session falls so far short of the requirements of the case, that in most essential particulars the recommendations of the Committee appear to have been passed over.

The Council of the Society of Public Analysts desires, therefore, to point out the

chief omissions in the Bill, and the principal directions in which it appears to require amendment.

The First Section of the Bill states that—

> "It shall be the duty of every local authority entrusted with the execution of the laws relating to the sale of food and drugs, to put in force from time to time, as occasion may arise, the powers with which they are invested, so as to provide proper securities for the sale of food and drugs in a pure and genuine condition, and in particular to direct their officers to take samples for analysis."

It appears to the Council that this Section gives no remedy for the existing unsatisfactory state of affairs, no means being provided or suggested for enforcing the performance of that which is recognised as a duty. Experience has shown, as is fully set forth in the Report of the Select Committee, that in spite of considerable pressure brought to bear by the Local Government Board, certain local authorities have persistently neglected to carry out the provisions of the Sale of Food and Drugs Acts.

The Second Section, which proposes to institute a *minimum* fine of £5 for a second or subsequent offence, carries into effect recommendation No. 16 in the Report of the Select Committee. This is one of the very few of the recommendations of the Committee which the Council feels itself unable to support, since the Council of the Society of Public Analysts is of opinion that the fixing of a minimum fine of £5, in all cases of second conviction, would be unduly binding on magistrates, who should be free to deal with each case on its merits, having regard to the great variety of circumstances requiring the consideration of the Bench which occur in connection with cases under the Acts.

With regard to the Fourth Section, the Council desires to draw attention to a recent case in which margarine was enclosed in a wrapper on which the word "margarine" was distinctly and legibly printed, but in which the significance of the word was diminished by the presence of other printed matter on the label. The Council therefore suggests that this Section might be improved by adding a provision that no other words or letters should be printed on the same wrapper.

With regard to Section 10, which relates to warranties, the Council of the Society of Public Analysts considers that, in order to ensure the conviction of the real offender in a case of adulteration, jurisdiction should be given to the Court before which the summons is heard, to call the giver of a warranty before it, should the warranty exonerate the vendor; and that proceedings should in such case be compulsorily instituted against the giver of the warranty. The Council also considers that no warranty should be accepted if given by a person abroad, or outside of such jurisdiction as it is possible to confer on the Court by Act of Parliament.

Section 12 (Sub-Section 1) proposes that the certificate of analysis required by the Sale of Food and Drugs Act of 1875 shall be in a form prescribed by the Commissioners of Inland Revenue, and proposes to repeal the Schedule to that Act relating to the form of certificates.

The Council of the Society of Public Analysts is of opinion that the form of certificate should not, as in the Act of 1875, be unalterably fixed, but dissents from

the proposal that the form should be prescribed by the Commissioners of Inland Revenue. The Council considers that the proper body to prescribe the form of certificates would be the Standing Committee or Court of Reference recommended by the Select Committee, the formation of which Court of Reference is not provided for in Mr. Chaplin's Bill, an omission to which attention is called hereafter.

Sub-Section 2 of Section 12 provides that the production by the defendant of a certificate by a public analyst shall be sufficient evidence of the facts therein stated (unless the prosecutor requires that such public analyst be called as a witness). The Council would suggest the desirability of providing that in the absence of the public analyst whose certificate is tendered by the defendant, and in the event of a material difference between the opinions expressed in that certificate and in the public analyst's certificate on which the prosecution was based, it should be compulsory on the Court to refer the portion of the sample retained by the Inspector to the Commissioners of Inland Revenue.

Having thus referred to some of the points suggested by the Government Bill, the Council wishes to call attention to certain of its omissions. The Select Committee made an important recommendation (No. 18)—

> " . . . . that the definition of the word 'food' as used in the Acts should be amended so as to include expressly all articles intended to enter into or be used in the preparation or flavouring of food."

This recommendation has not been adopted in the Government Bill, although its importance was very fully insisted upon. The present definition of food, as interpreted by the High Court, enables injurious, adulterated, or objectionable baking powders and certain other articles, to be sold with impunity, on the contention that they are not themselves "food," although they are sold for the express and avowed purpose of being introduced into food and consumed as such.

The most important omission, however, in the opinion of the Council of the Society of Public Analysts, is the failure to carry out recommendation No. 19 of the Select Committee, viz. :

> " . . . . that an authority should be constituted, who should act as a Court of Reference upon scientific and other questions arising under the Acts, and who should be empowered at their discretion to prescribe standards and limits of the quality and purity of food."

The report of the Select Committee deals with a very large number of questions on which, as a Committee, they refrain from making any definite recommendations, on the ground that such matters would properly be dealt with by the body whose formation they contemplated. They expressed the opinion—

> " . . . . that it would greatly facilitate the working of the laws as to the adulteration of food, and also serve the interests of traders, if standards or definitions of food were promulgated by competent authority"; and
> " . . . . that the question of fixing food standards should receive the attention of a specially-constituted scientific body familiar with questions of analysis and the chemistry of food."

Their recommendation was that such body or Court of Reference should—

> " . . . . be empowered to make such orders as they think proper respect-

ing standards of the quality and purity of food, and that such orders should, when confirmed by a Secretary of State, have the force of law"; and they were of opinion that ". . . . the formation of such an authority having the functions indicated would result in the removal of many practical difficulties met with in the administration of the Acts, and by rendering more precise the law affecting adulteration would obviate the costly litigation in which, under existing circumstances, traders and others have sometimes been involved."

It was recommended that the proposed—

" . . . . Court of Reference should take the form of a standing Departmental Committee appointed by the Board of Trade;" and that " . . . . such Committee should include the principal officer of the Government laboratory, nominees of the Local Government Board and Board of Agriculture, one or more analysts of repute, and representatives of the General Medical Council, the Institute of Chemistry, and the Pharmaceutical Society. Other scientists," it is added, "whose services are available, and whose presence on the Committee may be expected to lend weight to its decisions, should find places thereon."

It is further suggested that:

" . . . . representatives of the trading and manufacturing community should also be included."

In fact, this proposal as to the establishment of a Court of Reference having such powers as those alluded to, forms, from most points of view, one of the principal features in the report of the Select Committee; and the recommendation met with cordial and widespread endorsement. This being so, the Council of the Society of Public Analysts notes with very great regret the total omission from the Bill of any mention of such a Court or Committee. It is, in the opinion of the Council, essential for the success of any new legislation, not only that such a Court or Committee should be constituted, but that the Committee when formed shall include one or more *public* analysts. At the present time each individual public analyst is left to decide what does or does not constitute adulteration, what is or is not to be regarded as injurious to health, and what limits and standards are to be adopted in judging of the genuineness or otherwise of samples submitted to him. Disputed questions of the greatest scientific intricacy are now fought out, more or less imperfectly, in open Court at the expense of vendors or public authorities; and, as a consequence, questions which might have been settled, to the benefit of the community, many years ago, are still undecided, after more than twenty years' working of the Food and Drugs Acts.

The Court of Reference recommended by the Select Committee was originally suggested by the Society of Public Analysts, and the suggestion, as will have been seen from the quotations already given from their report, met with the entire approval of the Select Committee, who saw therein the means of solving the gravest difficulties which have hitherto arisen under the Food and Drugs Acts. The Council is clearly of opinion that, without such a Court or Standing Committee, any new legislation will be of little or no value, while, on the other hand, the institution of such a

Committee would afford the simplest means of ensuring the effective working of anti-adulteration legislation.

There are other points of omission in the Bill (such, for instance, as those connected with the Select Committee's recommendations affecting the colouring and mixing of butter substitutes), which the Council of the Society of Public Analysts does not feel itself directly called upon to discuss. Generally speaking, the Council is of opinion :

1. That the draft Bill introduced by the President and Secretary of the Local Government Board is unsatisfactory, inasmuch as it does not embody the most important recommendations of the Food Products Adulteration Committee, and that, if passed, it would not lead to the removal of the difficulties experienced in carrying out the present Sale of Food and Drugs Act.
2. That the recommendations of the Food Products Adulteration Committee, subject to but few modifications, should be embodied in any Bill which may be put before Parliament during the coming Session.
3. That the most important recommendation of the Select Committee, viz., recommendation No. 19, referring to the formation of a Court of Reference constituted substantially as laid down in the body of the report (with, however, the inclusion in its number of one or more public analysts) should be acted upon, if new legislation is to lead to satisfactory results.

A METHOD OF ESTIMATING GALLOTANNIC ACID BY MEANS OF THE POLARIMETER.

By R. F. Wood-Smith and Cecil Revis.

(*Read at the Meeting, December* 1, 1897.)

It is a well-known fact that difficulty has often been experienced in the Löwenthal method of estimating tannic acid, in properly filtering the gelatino-tannin precipitate, the filtrate from which is apt to remain turbid and to contain traces of tannic acid ; the method offers the further objection that it is not always easy to obtain a sensitive final reaction in the permanganate titration.

The method proposed by the authors removes these objections, and has the advantage of great rapidity ; but, at the same time, it must be borne in mind that it is based upon empirical data, that the experiments made were carried out in the case of gallotannic acid only, and that therefore varying results must be expected where other tannin material is employed.

The method consists in observing the lævo-rotation of a standard gelatin solution before and after treatment with known quantities of tannin material (the filtered liquids in each case being clarified by egg-albumin), when, at a constant

temperature, the quantity of gallotannic acid present (in the absence of other bodies optically active towards the polarized light) can be determined by a factor for the rotation difference.

It was found that at constant temperature the specific rotatory power of gelatin remained the same for any strength of solution up to 10 per cent., and it was further found that the difference between the rotatory power of the gelatin solution before and after treatment with tannin at constant temperature was directly proportional to the amount of gallotannic acid used, so long—and this was observed to be a most important condition—as sufficient excess of gelatin remained after treatment to cause a lævo-rotation of not less than seven divisions on the Ventzke scale.

The experiments for the determination of the factor were all carried out with a Schmidt and Haensch half-shadow quart-compensating polarimeter, an instrument which is constructed for use with "white light," as it was believed by the authors that this form of instrument was most generally employed for rapid work.

The gelatin used for the experiments, and for which the factors are calculated, is the well-known Coignet's gold label extra fine gelatin, since this was found to be constant in composition and in its specific precipitating power on gallotannic acid. It is extremely important that gelatin of this nature should be employed, since, as has been recently pointed out by P. Carles (*Ann. de Chim. Analyt.*, vol. ii. [10], 181, 182), different kinds of commercial gelatin precipitate very different quantities of gallotannic acid under the same conditions, and also possess different specific rotatory powers.

The temperature at which the experiments were carried out was 45° C., since at that point the specific rotatory power of gelatin only varies very slightly with changes of temperature, and it was found that differences of 3° or 4° produced no appreciable difference in the final results.

The gelatin solutions were also made up and kept at that temperature in a water-jacketed incubator, and all volumetric measurements occurring in the course of the experiments were made under the same conditions.

The details of the method and the calculated factors are here given:

A 1. 25 c.c. of an approximately 9 per cent. solution of gold label gelatin in water at 45° C. are transferred to an evaporating dish capable of holding about 100 c.c., which is placed on a boiling-water bath.

A 2. As soon as the temperature of the liquid has risen to about 60° C., 1 c.c. of the soluble albumin of a perfectly fresh egg is added, and the whole is allowed to attain the temperature of the water-bath, with constant stirring.

A 3. The liquid is kept at 100° C. for ten minutes, also with repeated stirring.

A 4. It is now allowed to cool down to about 50° C., when, if the supernatant liquid is seen to be quite clear, it is again heated up to 100° C. and filtered, the precipitate washed with boiling water, and made up to 50 c.c. at 45° C.; but if, as sometimes happens, the first treatment with albumin does not render the fluid free from opalescence, the above operation is repeated, when a clear liquid can always be obtained, especially if the warming on the water-bath be slightly prolonged.

A 5. It is advisable, if the bulk of liquor has during the process attained unduly large proportions, not to evaporate down, but to filter, wash as far as possible, and

make up to 50 c.c., and then to again wash the residue with boiling water, and make up the second washing to another 50 c.c.

A 6. The lævo-rotation of the clear filtrate is now taken at 45° C., to which must be added that of the second washing if necessary.

B 1. 25 c.c. of the same 9 per cent. gelatin solution are, as before, transferred at 45° C. to an evaporating dish, and a known quantity of the tannin extract added (which should for convenience contain between ·2 and 1 gramme of gallotannic acid).

B 2. The above is warmed on the water-bath for five to ten minutes, when the opalescent supernatant liquid is poured off into a second dish, the gelatino-tannin precipitate which adheres to the first basin being thoroughly worked about and washed with boiling water, and the washing added to the second basin.

B 3. This is now treated with egg-albumin in the same manner as the blank experiment (A 2-6), and is then filtered, made up to 50 c.c., and the lævo-rotation at 45° C. taken.

The difference between the rotations of A and B gives the measure of the gallotannic acid present. The experiments A standardize the gelatin solution, and the rotation so found may be taken as constant for the same solution for some time.

The following table states the gelatin differences of rotation caused by different amounts of gallotannic acid, and the factor which must be multiplied by the sugar units of difference (for white light) to give the amount of gallotannic acid present:

Weight of Gallotannic Acid Used = T.	Gelatin Rotation Difference in Sugar Units = R.	Factor $= \frac{T}{R}$.
0·900 grammes	13·50	0·0667
0·720 ,,	10·60	0·0679
0·600 ,,	8·90	0·0674
0·480 ,,	7·15	0·0671
1·000 ,,	14·90	0·0671

Mean factor $\frac{T}{R}$ for the above and numerous other experiments = 0·0673.

Addenda.—(1) It is important that the egg employed for clearing the liquid should in all cases be *perfectly* fresh, as otherwise the albumin does not coagulate properly, and the filtrate retains a slight opalescence.

(2) To ensure rapid filtration, a fluted filter should be employed; then the process takes place quickly, and a hot-water funnel is not necessary.

(3) After the tannin material has been added to the gelatin solution and warmed, the supernatant liquid should appear quite milky, this being an evidence that a sufficent excess of gelatin exists.

Discussion.

Mr. Hehner inquired whether the method was applicable to more than one kind of tannin, and, if not, to what particular kind of tannin it was applicable. It appeared to have the same difficulties as all other methods—in being useful only for one of the very numerous kinds of tannic acids. What was to be desired was a method for actually determining tannin, from whatever source it came.

Mr. ALLEN observed that a single method for the determination of tannin in any class of tanning material was as far out of reach as a universal method for the determination of all metals, for the variations in the properties of the so-called "tannins" were quite as great as the differences in the analytical behaviour of, say, iron, copper, tin, and zinc.

Dr. RIDEAL agreed with Mr. Hehner and Mr. Allen as to the variations in different tannins, and as to the difficulty of determining them. He had himself been in the habit of determining the quantity of potassium permanganate required by a solution of tannin (Loewenthal's method), and the quantity required by the tannin solution after treatment with hide-powder, representing the quantity of organic matter in the solution before and after treatment, the difference between the two being the actual weight of organic matter present as tannin, or matter absorbable by hide-powder. The use of a very pure gelatin seemed to have an advantage over hide-powder, inasmuch as there was a good deal of difficulty in obtaining uniform hide-powder. The use had been recently suggested of a compound of gelatin and formalin, which absorbed tannin in the same way as gelatin, and which might possibly have a more constant composition.

Mr. A. C. CHAPMAN thought Mr. Allen's remark too sweeping. It was perfectly well-known that there were different kinds of tannin, which behaved differently in regard to their action on gelatin; but if separate processes could be devised to give accurate or approximately accurate results with, for example, bark, tea, hops, and like materials respectively, each of these processes would be extremely useful, even if it were not applicable to more than one kind of material.

The PRESIDENT observed that the method, although it might not be applicable to different classes of tannin equally, was certainly an interesting one, and one which opened up new avenues of investigation.

Mr. WOOD-SMITH admitted that the method was only applicable for the particular kind of tannin employed, viz., the ordinary purified commercial gallo-tannic acid, and that, further, the presence of optically-active bodies other than tannic acid necessarily interfered with the results. It had, however, proved very useful to the authors under circumstances involving the use of one class of tannic acid only, and factors could no doubt be determined for any other variety of tanning material. In reply to a question put by Mr. Richmond, he said that the normal weight of sugar solution for the polarimeter employed in the experiments was 26·048 grammes.

A BUTTER EIGHTEEN YEARS OLD.

By E. G. CLAYTON.

(*Read at the Meeting, December* 1, 1897.)

THE butter to which these remarks apply was the subject of a reference-case under the Sale of Food and Drugs Act in 1879. In that year it was analysed by Mr. Hehner, who has kindly given me permission to mention that he found it to yield 87·75 per cent. of insoluble fatty acids, while it contained normal amounts of water, curd, and salt, and evidently was perfectly genuine.

Since 1881 the bottle containing the residual portion of the sample has been in my keeping, and the following are the results of the examination to which I have submitted this old butter. It should be premised that the quantity was very small, otherwise a more complete investigation would have been made. The sample had rather an offensive odour, and was considerably discolored. During most of the time the bottle was kept in a dark cupboard, but the stopper, being broken, fitted imperfectly, so that there was ample opportunity for oxidation.

ANALYSIS:

Melting Point.	Density at 100° C. (Water at 15·5° C.).	Insoluble Fatty Acids.	Soluble Fatty Acids.	Reichert number (5 grammes used).	Koettstorfer numbers.	Hübl (Iodine absorbed).	Maumené.	Rancidity.
33° C.	·8742*	85·72%*	7·36%	22·36 c.c.* $\frac{N}{10}BaH_2O_2$.	Required 23·47% KOH; = 239·0, saponification equivalent.	(*a*) Estimated in 1895: 25·68%.* (*b*) Estimated in 1897: 25·09%.	Rise of temperature = 22°C.	100 grms. required 160·3 c.c. normal KOH.

The numbers with asterisks were obtained by me in January, 1895, the remainder in October, 1897.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

The Adulteration of Milk with Saccharose Solutions. Cotton. (*Bull. de Pharm. de Lyon*, August, 1897; through *Jour. Pharm. Chim.*, 1897, vi., 362, 363.)—The following is given as a rapid test for detecting the addition of saccharose solutions to milk: Ten c.c. of the suspected milk are mixed with 0·5 gramme of powdered ammonium molybdate, and 10 c.c. of dilute hydrochloric acid (1 : 10). In a second tube 10 c.c. of milk of known purity, or 10 c.c. of a 6 per cent. solution of lactose, are similarly treated. The two tubes are placed in a water-bath, and the temperature gradually raised. At about 80° C. the milk, if adulterated with saccharose, assumes an intense blue colour, whilst the genuine milk, or lactose solution, remains unaltered. On boiling, these also turn blue, but to less extent than the adulterated milk.

With milk containing only 1 gramme of saccharose per litre, the reaction is well marked, but the author states that the amount used for adulteration is never less than 6 grammes per litre. C. A. M.

The Composition of Asses' Milk. A. Schlossmann. (*Zeit. Phys. Chem.*, 1897, xxiii., 258).—The author gives the results of his analyses of sixteen samples obtained from one establishment in Dresden. The density varied from 1·031 to 1·036, and the mean percentage results of the total solids were 11·15; of the ash, 0·399; and of the sugar, 4·94. The total nitrogen varied from 0·22 to 0·27 per cent., of which 86 per cent. belonged to albuminoid substances (precipitated by trichloracetic acid or salicyl-sulphonic acid). The limits of fat, of which the globules were very small, were 0·15 and 0·6 per cent. One c.c. of the milk required for neutralization 0·06 c.c. of decinormal sulphuric acid with phenol-phthalein as indicator, and 0·404 c.c. with methyl orange or turmeric as indicator. C. A. M.

On the Volumetric Determination of Casein in Milk. G. Deniges. (*Jour. Pharm. Chim.*, 1898, vii., 9-12.)—This is a supplementary note on the author's volumetric process (ANALYST, xxii., 11). In the titration of milk rich in calcium salts, a turbidity occurs after the addition of ammonia which prevents the end-reaction from being clearly observed. This is obviated by the addition of a little ammonium oxalate, which does not exercise any disturbing influence. The modified process is as follows: Twenty-five c.c. of the milk are mixed with 5 c.c. of a saturated solution of ammonium oxalate, 20 c.c. of the decinormal mercuric-potassium iodide solution, and 2 c.c. of acetic acid, the volume made up to 200 c.c. and the liquid filtered. To 100 c.c. of the clear filtrate are added 10 c.c. of a solution of potassium cyanide equivalent to a decinormal (or approximately decinormal) solution of silver nitrate, and 12 to 15 c.c. of ammonia, and the liquid titrated with the silver nitrate solution until there is a permanent turbidity. The number of c.c. used = q.

A blank determination is made to determine the exact value of the silver nitrate solution. Ten c.c. of the cyanide solution, 12 to 15 c.c. of ammonia, and 10 c.c. of the mercuric-potassium iodide solution, are mixed with 100 c.c. of water and titrated as before with the silver nitrate. The number of c.c. = c, and the casein in the milk corresponds to $q - c$. When the silver nitrate is exactly decinormal, $c = 4·8$ c.c. The value of $q - c$, expressed in tenths of a c.c., is then obtained from the table or the formula given in the former paper. C. A. M.

A Contribution to the Study of Butter. K. Farnsteiner and W. Karsch. (*Zeit. für Untersuch. der Nahrungs-und Genussmittel*, 1898, 16-21.)—The authors call attention to a case of butter of unquestionable purity showing abnormally low Reichert-Meissl and saponification numbers. Different samples of the butter, which came from a farm in Holstein, gave the following numbers:

Refractometer number (25° C).	Reichert-Meissl number.	Saponification number.
55·0	23·98	220·27
55·0	23·68	219·20
55·0	22·80	218·53
55·0	22·74	218·50

The case was further inquired into, and 25 cows out of the 180 kept at the farm were selected as corresponding to the whole number as regards the average period of

lactation. The milk from these being treated separately, yielded a butter which gave the same abnormal results, viz. :

Refractometer number. (25° C).	Reichert-Meissl number.	Saponification number.
53·0	22·16	220·40
53·2	22·22	221·75
53·0	22·11	219·74

The relation of the refractometer number to the iodine number is shown in the following figures :

	Refractometer number.	Iodine number.	Reichert-Meissl number.	Saponification number.
October 21, from 180 cows	55·0	49·57	22·80	218·53
October 26, ,, 25 ,,	53·0	40·00	22·11	219·74

The case corresponds to that reported from Hameln by Vieth, and is doubtless due to the cows having been for a long time in milk. H. H. B. S.

Detection of Sesame-oil in Butter and Margarine. P. Soltsien. (*Pharm. Zeit.*, 1897, xlii., 837 ; through *Chem. Zeit. Rep.*, 1897, 325.)—The author calls attention to the fact that when furfuraldehyde, or at least the German official alcoholic solution thereof, is mixed with hydrochloric acid (sp. gr. 1·19), it yields of itself a red coloration, which appears slowly in the cold, but quickly on warming ; and the tint is very similar to that produced by a small amount of sesame-oil. The only difference between the two is that the former develops more slowly, soon changes to the colour of permanganate, and finally assumes a bluer tone, which is fairly permanent. F. H. L.

On the Detection of Ergot in Flour. A. Miller. (*Jour. Soc. Phys. Chim.*, xxviii., 824 ; through *Jour. Pharm. Chim.*, 1897, 553.)—The author has met with a sample of flour containing only a trace of ergot (not more than 0·1 per cent.), which, nevertheless, imparted to the alcoholic extract a clear rose coloration as pronounced as though the proportion of ergot had been 1 per cent. On examination, the flour was found to contain particles of the husk of the grain of a bluish-green shade, which assumed a reddish tint on treatment with acidulated alcohol, and imparted the same colour to the alcoholic extract. The difference in shade between the colour produced by this flour and that containing ergot was only distinguishable in concentrated solutions, when the former was rose-red whilst the latter was brick-red. C. A. M.

TOXICOLOGICAL ANALYSIS.

On the Detection of Phosphorus in Toxicological Work. H. Natterman and A. Hilger. (*Forsch. Ber.*, 1897, iv., 241-258.)—The methods employed for the detection of phosphorus in forensic work are : (1) Scherer's, which depends upon the fact that steam containing phosphorus vapour reduces silver nitrate. The substance under examination is mixed with water, acidified with sulphuric acid, and warmed at 30° to 40° C., whilst strips of the reagent paper are suspended in the mouth of the

flask. (2) Mitscherlich's, which is based on the volatility of elementary phosphorus in steam, and its becoming luminous on contact with oxygen. (3) Dussart-Blondlot's, which is especially suitable for the detection of phosphorus in an oxidized state. It depends on the fact that phosphorus, and many of its compounds, when treated with nascent hydrogen, yield a gas which, when ignited, gives a flame the inner cone of which is of a deep-green colour.

With regard to Scherer's reaction, the author points out that many substances may cause a darkening of the silver nitrate paper, and that the test must be regarded as a negative one (the absence of any discoloration proving the absence of free phosphorus) rather than as a positive one, unless phosphoric acid can be identified in the blackened paper.

In Mitscherlich's test the experiments described at length in the paper show that in the distillation of the phosphorus in the ordinary way the amount recovered is only a fraction of the whole, though the yield increases as the quantity of phosphorus present becomes larger. This is largely due to a certain amount of oxidation taking place within the flask and the non-volatility of the oxidation products. To obviate this the author has devised a modification of the process, in which a current of carbon dioxide is led into the flask during the distillation. The steam carrying the phosphorus passes upward through a narrow tube which is bent twice at right angles, first horizontally, then downwards, is condensed in a vertical condenser, and falls into an Erlenmeyer flask. Connected with the side-tube of the flask is a suction-pump, by means of which air is drawn into the horizontal part of the narrow tube through a smaller tube fused on, and closed when not in use by an indiarubber tube and spring clamp.

In this way the oxidation takes place entirely in the tube, whilst the interior of the distillation-flask remains absolutely dark, and it is possible to recover in the distillate over 90 per cent. of the phosphorus present in the original substance. The smallest quantity of phosphorus capable of detection by the Mitscherlich process is 0·00006 gramme.

Where oxidation is prevented by drying, or by the course of putrefaction, a small amount of free phosphorus can be detected in organic matter long after it has been mixed with it. Thus, 0·003 gramme of phosphorus was mixed with organic matter in a state of putrefaction, and could still be detected after a lapse of six months.

In the Dussard-Blondlot test certain substances, noticeably ether and proteid derivatives, interfere with the reaction. This is obviated by passing the phosphuretted hydrogen first through potash to remove sulphuretted hydrogen, and then into silver nitrate solution and applying the test to the precipitate of phosphor silver.

The author recommends the following modification of the test as more simple and sensitive than the ordinary process: The filter containing the silver phosphide precipitate is placed, together with a little pure zinc and some water, in a small flask fitted with a cork with three perforations. Through two of these pass tubes bent at right angles, whilst a third is for a thistle funnel. One of the tubes is connected with a Kipps' hydrogen apparatus, the gas generated in which is proved by the spectroscope to be free from phosphorus, whilst the other tube is connected with a U-tube filled with pumice saturated with potash, and in which is inserted the platinum jet.

Hydrogen is then generated within the flask by introducing through the thistle funnel a few c.c. of dilute sulphuric acid (1 : 5), and this is swept onwards by means of the current of hydrogen from the Kipps' apparatus, and a strong flame is obtained at the jet. The smallest amount of phosphorus capable of detection by this reaction with the naked eye is 0·00000006 gramme, but even less than this can be recognised with the spectroscope.

The chief drawback to the process is the length of time required to reduce phosphorus in the form of acids to phosphuretted hydrogen. From ten to fourteen days are required for the reduction of only a few milligrammes, and then never more than one-fifth of the total amount present is converted. The author finds, too, that the precipitate of silver phosphide does not account for the whole of the phosphorus, and that the solution of silver nitrate often contains as much as the washed precipitate. He suggests that advantage may be taken of the complete absorption of phosphuretted hydrogen in a solution of copper chloride. Thus, a solution prepared by dissolving 4 grammes of pure copper chloride in 20 c.c. of hydrochloric acid (sp. gr. 1·19), adding 30 c.c. of a 12 per cent. solution of potassium hydroxide, and pouring off the liquid from the crystals separating, absorbs the gas completely, and readily parts with it again on warming. C. A. M.

ORGANIC ANALYSIS.

Estimation of Small Quantities of Methyl Alcohol, Formaldehyde, and Formic Acid. Nicloux. (*Bull. Soc. Chim.*, 1897, xvii., 839, 840.)—This is an extension of the author's process for determining ethyl alcohol in very dilute solution, based on the reduction of potassium bichromate by the alcohol in the presence of sulphuric acid (*Bull. de la Soc. Therap.*, iii., 860). In each case the solution under examination must contain only one of these bodies, and must also be free from other organic substances capable of reducing bichromate. In the determination, 5 c.c. of pure concentrated sulphuric acid are added to 5 c.c. of the solution, the mixture heated for a minute and titrated with standard bichromate (the strength of which varies according to the substance to be determined) until a green tint is obtained. It is advisable to compare the colour with that of a series of standard colour samples recently prepared so as to obtain the exact value of the standard solution.

The strength of the bichromate solution is : for methyl alcohol, 19 grammes ; for formaldehyde, 17 grammes ; and for formic acid, 11 grammes of bichromate per litre respectively. In each case 2 c.c. corresponds to 5 c.c. of a solution containing 1 gramme of the substance per litre (*cf.* ANALYST, xii., 25 and xxii., 161 and 263).

C. A. M.

On the Detection of Formalin. A. Jorissen. (*Jour. Pharm. de Liège.* 1897, iv., 257 ; through *Bull. de la Soc. belge*, 1897, 211, 212.)—The author gives a summary of different tests used for the detection of formalin, but objects to all of them with the exception of Hehner's reaction (ANALYST, xxi., 95) on the ground that they are not peculiar to formaldehyde. He finds that in the case of the last it is possible

to replace the milk by certain alkaloids, of which several give characteristic reactions of extreme sensitiveness. Thus, on placing a little morphine hydrochloride in a porcelain basin, adding a few drops of concentrated sulphuric acid, and touching the mixture with the end of a glass rod previously dipped in a solution of formaldehyde, even if exceedingly dilute, a purple colour is produced which changes to an indigo blue. C. A. M.

Analysis of Fats. Extraction of Cholesterin and Phytosterin. A. Bömer. (*Zeit. für Untersuch. der Nahrungs-und Genussmittel*, i., 21-49.)—The following process is recommended: 50 grammes of fat are saponified with 100 c.c. of alcoholic potash solution, the solution diluted with 200 c.c. of water, and the whole shaken for from a half-minute to a minute with 500 c.c. of ether. After standing for two or three minutes, the etheric extract is separated and distilled. The soap solution is then again extracted two or three times with 200 to 250 c.c. of ether, each extract being distilled off as before. After the ether has all evaporated, a little alcohol usually remains in the residue, and this is removed by blowing air through it, while the vessel containing it is immersed in a bath of boiling water. The residue still contains a little unsaponified fat, which is removed by a further saponification with 10 c.c. of alcoholic potash. The contents of the flask are now washed out into a separating funnel with 20 c.c. of water, 80 to 100 c.c. of ether added, the whole shaken for half a minute, allowed to stand for a few minutes to separate, the aqueous-alcoholic portion drawn off, and the etheric extract washed three times with 5 to 10 c.c. of water. After removal of the last wash-water, the etheric extract is filtered into a small beaker or Erlenmeyer flask, and the ether slowly evaporated off. On drying in the water-bath, a crystalline residue is obtained containing the cholesterin and phytosterin, from which these bodies can be obtained in a pure state by crystallization.

Cholesterin can be easily distinguished from phytosterin by the form of the crystals and the manner of its crystallization. If, however, both bodies are present together, the mixture crystallizes in one form only, the crystals either approximating to the form of phytosterin crystals, or, if cholesterin is present in the greater quantity, differing in form from the pure crystals of either body. H. H. B. S.

On the Cause of the Rancidity of Fats. A. Mjöen. (*Forsch. Ber.*, 1897, iv., 195-203.)—The author's experiments, which were chiefly made with butter, olive-oil, and liver-oils, confirm the statements of other observers (*e.g.*, Spaeth, ANALYST, xxii., 46); but it is further shown that there is a marked difference between the oxidation changes caused in the composition of the fat by a current of air, and by the action of direct sunlight. Thus in the case of butter placed in the sun for three days the acidity number rose from 1·2 to 10·7, whilst the iodine number fell from 32·9 to 30·7; whereas the same butter, subjected to the action of a current of air alone, did not show that degree of acidity until after five weeks, and then the iodine number had fallen to 19·8. There is also a difference in the appearance of the oxidized fat, butter becoming rancid in the sunlight assuming a deep yellow colour, that

oxidized by the air keeping its colour for two or three weeks, and then becoming snow-white. The author suggests that this change may be due to the action of an enzyme similar to those which cause the discoloration of freshly-cut apples, etc., to which the name of "oxydase" has been given. Although he has proved that bacteria and moulds do not act upon fresh fat, he is not prepared to say that they play no part in a further change when once a decomposition process has commenced.

Ritsert (*Natur. Woch.*, v., 196) asserts that oxygen does not produce rancidity in fat in the absence of light; but this the author considers is conclusively disproved by his experiments. These also show that the decomposition is accelerated by raising the temperature (45° C.). C. A. M.

Japanese Wood-Oil (Tung-Oil). (*Chem. Tech. Zeit. Lack u. Farb. Ind.*; through *Deutsche Chem. Zeit.*, 1897, xii., 419. Also *Rev. Chim. Ind.*, 1897, viii., 338.) —This glyceride oil is obtained in China and Japan from the seeds of the *Aluerites cordata*, and it is being introduced into Europe as a substitute for linseed-oil in varnishes and paints. It is a clear, yellow, viscous liquid, with an odour resembling linseed-oil; when freshly prepared it is extremely poisonous; and it is used for the adulteration of gurgun balsam. Glacial acetic acid produces a turbidity at 47° C. When 5 grammes are treated with 2 c.c. of chloride of sulphur and an equal volume of carbon disulphide, the mixture solidifies on stirring for a minute and a half at ordinary temperatures; but the paste is not so hard as that yielded by linseed or castor-oil. A thin layer exposed to the air dries in about twenty-four hours to an opaque white film. If 4 grammes are heated (temperature not specified) in a 7 cm. dish, a skin forms at the edges in fifteen minutes, which in two hours becomes so tough that the contents will not fall out as the vessel is inverted; while during four hours the gain per hour is 0·36 per cent. When heated with 0·5 per cent. of litharge and a current of air passed through it, the oil acquires the consistency of a jelly in about fifteen minutes. It yields a solid elaidin. Warmed with silver nitrate for fifteen minutes, a reddish-brown colour is produced. Strong sulphuric acid converts it into a black mass; nitric acid (sp. gr. 1·4) into a solid body in two minutes, which finally becomes dark and friable. If 1 gramme of the oil is dissolved in 5 c.c. of chloroform and shaken with 5 c.c. of a saturated solution of iodine in the same liquid, a thick paste is soon produced. The constants of tung-oil are as follows:

Specific gravity at 15·5°	0·8385
Solidifying point (about)	17°
Iodine number	165·7
Saponification number	194
Specific temperature reaction	372
Insoluble fatty acids	96·4%
Unsaponifiable matter	0·44%
Free fatty acids	3·84%
Melting and solidifying point of acids	37°
Iodine number of acids	150·1

F. H. L.

[According to *Rev. Chim. Ind.* (*loc. cit.*), the free acid corresponds to 1·6 per cent. of KHO, and the sp. gr. at 30° C. is 0·9405. Deering (*Imperial Inst. J.*, 1896,

303) gives the bromine absorption as 98 per cent.: it should seem that there are at least two varieties, pale and dark; two kinds also are distinguished in China, coming from Canton and Hankow respectively. Lippert (*Zeits. Angew. Chem.*, 1897, 779) states that owing to the large amount of free acid it contains, tung-oil thickens (or "sets up") in presence of oxide pigments with inconvenient rapidity.—ABS.]

The Determination of Fat and Casein in Fæces. **H. Poole.** (*Jour. Amer. Chem. Soc.*, 1897, xix., 877-881.)—The various methods of analysing fæces have been summarized by Grausnitz (*Zeit. f. Biol.*, 1894, 328), but the author takes exception to all of them on the ground that the separations are only imperfect. Thus, the fat, which in each case is determined by extracting the dried fæces with ether and weighing the residue, contains also biliary and other products, whilst hitherto no method of separating casein from epithelium cells has been described.

Having occasion to make a number of determinations of the amount of undigested fat and casein in the fæces of children fed on milk, the author devised the following process, which he claims gives results perfectly comparable among themselves, and much nearer the truth than those of any of the older methods:

The ether extract, containing the fat, cholesterol and coloring matters from the bile, is evaporated at 100° C. and the residue dried at 110° C. It is then saponified with alcohol potash (which as a rule leaves only a trifling amount unsaponified), water is added, and the alcohol expelled by boiling. More water is added if necessary, and the solution filtered. The filtrate is extracted twice with an equal volume of ether in a separatory funnel. The liquid, thus freed from cholesterol, is evaporated nearly to dryness, water added, and the fatty acids liberated, determined in the usual way and calculated into fat.

In the determination of the casein, the fæces are extracted successively with ether, water, and alcohol, and dried, the three solvents removing most of the nitrogenous substances other than undigested casein and epithelium cells. The residue, which also contains insoluble fatty acid compounds (usually salts of iron, aluminium and calcium), is digested for several hours at 50° C. in a mixture of hydrochloric acid thirty parts, and water seventy parts, which dissolves the casein and leaves the epithelium cells and other substances. After cooling, the liquid is filtered, evaporated, and the nitrogen in the residue determined by Kjeldahl's process, and calculated to casein.

In a full analysis the amount of fatty acids in the insoluble soap would also be determined, but as these usually represent digested or partially changed fats, they did not come within the scope of the author's work, which was concerned only with the undigested portions. C. A. M.

A New Reagent for Urinary Albumins. **Bourceau.** (*C. R. Soc. de Biol.*, 1897, 317; through *Bull. de la Soc. belge*, 1897, 248.)—Urine may contain coagulable albumins or proteoses which have not the same clinical significance. Oxyphenylsulphonic acid containing a trace of salicyl-sulphonic acid will detect the albumins in the presence of the other compounds. A drop or two of the reagent added to 1 c.c.

of the urine gives an opaque white precipitate with albumins and alkali-albumins, whilst no precipitate is obtained with proteoses, peptones, alkaloids, antipyrin, salicylates, phosphates, or urates. C. A. M.

The Detection of Santonin in Urine. L. Daclin. (*Jour. Pharm. Chim.*, 1897, vi., 534.)—From 30 c.c. to 40 c.c. of the urine are treated first with lead acetate, then with crystalline sodium sulphate and filtered. The clear filtrate is divided into two parts, and evaporated in porcelain basins. The residue in one is gently warmed with one or two drops of sulphuric acid, and should santonin be present, gives an immediate violet coloration. To the other residue a few drops of alcoholic potash are added, which gives with santonin a rose colour. Or the urine may be extracted with chloroform, the solvent evaporated, and the residue tested as above. Rhubarb gives a negative result with these reagents. C. A. M.

The Determination of Phenols in Urine. J. Amam. (*Rev. Med. Suiss-romande*, xvi., 657; through *Jour. Pharm. Chim.*, 1897, vi., 361.)—The method described is a colorimetric one, based on the reaction given by phenols with Millon's reagent, and with para-diazo-benzene-sulphonic acid. Millon's reagent gives a reddish colour on warming, which however does not remain long without alteration. The other test is more characteristic and more sensitive. On adding para-diazo-benzene-sulphonic acid to phenols in alkaline solution (sodium carbonate), acid or neutral azo-benzene-phenyl sulphonates are produced, the colour of which varies from orange to red, according to the nature of the phenol. Neither of the tests can be applied to the urine itself, and the phenols must first be separated by adding sulphuric acid and distilling. The aqueous solution of diazo-benzene-sulphonic acid must be prepared immediately before use, but it has the advantage over Millon's reagent of giving the reaction in the cold, and of producing a much more permanent coloration. C. A. M.

The Analysis of Glycero-phosphates. A. Astruc. (*Journ. Pharm. Chim.*, 1898, vii., 5-8.)—For the determination of the phosphoric acid a known volume of a solution of the glycero-phosphate is neutralized with sulphuric or hydrochloric acid, with methyl orange as indicator, and the solution then titrated with a standard solution of alkali and phenol phthalein. Taking calcium glycero-phosphate as the type, the reactions are indicated by the equations:

$$2PO\begin{matrix}\diagup O \\ \diagdown O\end{matrix}\!\!>Ca + H_2SO_4 = CaSO_4 + (PO_4C_3H_7O_2)_2CaH_2$$
$$\qquad\qquad\quad \diagdown O{-}C_3H_7O_2$$

in which one molecule of sulphuric acid corresponds to two molecules of phosphoric acid,

$$\text{and } (PO_4C_3H_7O_2)_2CaH_2 + 2NaOH = (PO_4C_3H_7O_2)_2CaNa_2 + 2H_2O,$$
$$\text{or } (PO_4C_3H_7O_2)_2CaH_2 + 2NaOH = PO_4C_3H_7O_2Ca + PO_4C_3H_7O_2Na_2 + 2H_2O,$$

in which one molecule of phosphoric anhydride corresponds to two molecules of soda-

From this the quantity of phosphorus pentoxide in solution can be calculated. The results thus obtained are about 0·5 per cent. lower than those obtained by calcining a known weight of the glycero-phosphate, dissolving the ash in hydrochloric acid, and determining the phosphorus as magnesium pyrophosphate, so that the process gives very approximate figures in a very short time.

Glycero-phosphates of calcium, when dissolved, are alkaline to methyl orange, but sometimes acid and sometimes alkaline to phenolphthalein. The acid salts are almost entirely soluble without residue, whereas the alkaline salts dissolve with more difficulty and give a slightly turbid solution, but the alkalinity is always excessively feeble. Acidity to phenolphthalein indicates a certain amount of decomposition during the preparations of the calcium glycero-phosphate.

In the case of adulteration to any extent of calcium glycero-phosphate with disodium phosphate, the solution would be strongly acid to phenolphthalein, and the quantity of sulphuric acid required for neutrality with methyl orange would be far from being equivalent to the quantity of soda subsequently required for neutrality with phenolphthalein. C. A. M.

On Retamine, a New Alkaloid. Battandier and Malosse. (*Jour. Pharm. Chim.*, 1897, vi., 241, 242.)—The authors have extracted from the young leaves and the bark of the *retama sphærocarpa* by the ordinary methods of extraction an alkaloid, to which they have given the name of *retamine*. One kilogramme of the fresh plant yields about 4 grammes of the alkaloid.

Retamine crystallizes in long needles on cooling a saturated solution of it in ether or petroleum spirit, and in prismatic plates on cooling an alcoholic solution, whilst spontaneous evaporation of the alcoholic solution yields rectangular tablets. It has a very bitter taste and has no marked physiological action. It melts at 162° C., and decomposes at a higher temperature. It gives the general reactions for the alkaloids, and yields a characteristic precipitate with bismuth potassium iodide. Platinic chloride does not precipitate it. With ammonium sulphate it gives feebly the reaction of sparteine. It forms well-marked salts, which crystallize readily, and which usually contain for one molecule of retamine either one or two molecules of monobasic acid. The mean results of the elementary analysis correspond to the formula $C_{15}H_{26}N_2O$; so that retamine appears to be an oxysparteine, although different to the known artificial oxysparteines. C. A. M.

A Delicate Test for Ammonia and Organic Matter containing Ammoniacal Nitrogen. E. Riegler. (*Bul. Soc. Scientc den Bucuresci*, 1897, vi., 335; through *Chem. Zeit. Rep.*, 1897, 307.)—Para-diazo-nitraniline forms a very sensitive reagent for detecting ammonia, ammonium salts, and all nitrogenous organic compounds which evolve ammonia on treatment with strong bases (*e.g.*, albuminoids and some alkaloids). One gramme of paranitraniline is dissolved by heating with 20 c.c. of water and 2 c.c. of hydrochloric acid, the liquid is diluted and well shaken with 160 c.c. of water, and, when it is cold, 20 c.c. of a 2·5 per cent. solution of sodium nitrite are added. Ten c.c. of the liquid to be tested are treated with ten or fifteen

drops of the reagent, and 10 per cent. caustic soda solution is slowly dropped in. If ammonia is present, an orange turbidity is produced; and on agitation the liquid becomes yellow, orange, or red, according to the amount present. On acidifying with sulphuric acid the solution loses its colour, and a mass of yellow, microscopic, needle-shaped crystals collects on the surface. This body is very soluble in alcohol, and on adding a little caustic soda it gives an intense red violet coloration. The reagent becomes cloudy on keeping, but after filtration it is still serviceable.

F. H. L.

A New Process for the Determination of Crude Fibre in Food Stuffs. **J. König.** (*Zeit. für Untersuch der Nahrungs-und Genussmittel*, i., 3-16.)—This paper is the outcome of endeavours to devise a process which shall furnish crude fibre as free as possible from pentosans. The process is based upon the following results of experiments:

1. A temperature of 120° to 130° C. is not sufficient to ensure the solution of the pentosans in all vegetable substances. The most suitable temperature lies between 130° and 140° C. A higher temperature causes the hexosans to be more strongly attacked.
2. The complete solution of the pentosans by the glycerin process depends less upon the proportion of sulphuric acid added to the glycerin (within the limits of 1 to 3 per cent.) than upon the length of time allowed for the action. A 3 per cent. addition of sulphuric acid effects the solution quicker than a 1 per cent., but not proportionately to the increased quantity.
3. 200 grammes of glycerin of 1·230 specific gravity (12·5 per cent. water and 87·5 per cent. glycerin) for 3 grammes of substance appears to be the most suitable proportion, as well as the best strength.
4. The pentosans are brought into solution quicker by the employment of higher temperatures and larger proportions of acid than by the employment of lower temperatures and less acid. The most suitable length of time for boiling is on the average one hour at 131° to 133° C., reckoned from the commencement of ebullition, or half an hour at 135° to 137° C.

The process is carried out as follows: Three grammes of the air-dried substance are placed in a porcelain basin with 200 c.c. of glycerin of 1·230 specific gravity containing concentrated sulphuric acid in the proportion of 20 grammes per litre. After mixing, the basin is placed in a steam bath and subjected for one hour to a temperature of 137° C., corresponding to a pressure of three atmospheres. The lamp is then removed, and when the temperature has fallen to from 80° to 100° C., the basin is taken out, 200 to 250 c.c. of boiling water added, and the contents filtered through an asbestos filter. Should the fluid filter slowly, it must be maintained at a temperature of 80° to 90° C. throughout the filtration. A cold solution of glycerin filters badly.

The residue is washed first with 300 to 400 c.c. of boiling water, then with 50 c.c. of warm, 93 per cent. alcohol, and lastly with a warm mixture of ether and alcohol, until the washings are quite colorless. The filter is then dried and weighed, after which it is incinerated and re-weighed, the difference between the two weights giving the ash-free crude fibre.

The extraction may also be carried out at the ordinary atmospheric pressure by boiling in a flask fitted with a reflux condensor. The pentosan (furfural) determination is carried out by the phloroglucin method of Tollens. The process has been tried side by side with Henneberg's method, and the results of a number of determinations, calculated in each case upon the material in the dry state are given in the following table:

	In the original substance.		Henneberg's Process.			Pressure with Glycerin of 1·230 specific gravity and 2 p. c. Sulphuric Acid.			1·230 specific gravity and 2 per cent. Sulphuric Acid.		
	Pento-	Nitrogen.	Crude Fibre.	Pentosans in Crude Fibre.	Nitrogen Fibre.	Crude Fibre.	Pentosans in Crude Fibre.	Nitrogen Fibre.	Crude Fibre.	Pentosans in Crude Fibre.	Nitrogen Fibre.

Fairly good results can also be obtained by heating with 200 c.c. of acidified glycerin in an open basin, only in this case it is more difficult to maintain an even temperature between 135° and 137° C. It can, however, be kept within the limits of 133° and 140° C. for half an hour, and the following results, calculated upon the dry substance, were obtained in this way:

Feeding Stuffs.	Crude Fibre.	Pentosans in the Raw Fibre.	Nitrogen in the Raw Fibre.	Feeding Stuffs.	Crude Fibre.	Pentosans in the Raw Fibre.	Nitrogen in the Raw Fibre.
	Per cent.	Per cent.	Per cent.		Per cent.	Per cent.	Per cent.
Rye straw	44·71	1·78 1·52	0·14	Wheat bran	8·51 9·09	0 0	0·09 0·11
Grass hay	25·90 25·84 25·95	0·47	0·37	Brewers' grains	13·98 13·24	0 0	0·11

The superiority of the glycerin process to the older one of Henneberg is shown very clearly in the following table, from which it appears that whereas by the Henne-

berg process considerable quantities of pentosans remain undissolved, varying with each material up to 40·73 per cent. of the pentosans originally present, by the glycerin process the quantity remaining undissolved does not exceed 6·62 per cent.

	Pentosans remaining in the Crude Fibre in percentage of the pentosans originally present.			1. Crude Fibre by Old Process.	2. Containing Pentosans.	3. Crude Fibre free from Pentosans by old Process. (1-2)	4. Crude Fibre by Treatment with Glycerin.

H. H. B. S.

INORGANIC ANALYSIS.

Volumetric Estimation of Gold. J. Petersen. (*T. Physik og Chem.*, 1897, i., 341; through *Chem. Zeit. Rep.*, 1897, 307.)—The author finds that in an acid solution gold can only be titrated accurately by means of oxalic acid or ammonium oxalate when the whole process is conducted in an atmosphere of carbon dioxide. In the presence of oxygen the finely-divided metal appears to behave like platinum-black, oxidizing the oxalic acid, and causing the volume of standard solution employed to be from 18 to 73 per cent. above the theoretical. By the use of sodium oxalate in a neutral liquid, however, perfectly satisfactory results may be obtained. The gold is dissolved in aqua regia containing a large proportion of hydrochloric acid, sodium chloride introduced, the mixture evaporated to dryness, taken up in water, and again dried down. The excess of oxalate is titrated with permanganate as usual. The chlorides of mercury and copper do not affect the process; but sufficient sodium oxalate must be added in the first instance to hold any copper oxalate in solution after the reduction of the gold. The method is not available when the gold is combined with platinum. F. H. L.

Volumetric Estimation of Antimony. J. Hanus. (*Vestnik kral. ceske spolecnosti nauk*, 1897 [II.], No. 40, 1; through *Chem. Zeit. Rep.*, 1897, 324.)—0·2 to 0·3 gramme of precipitated sulphide of antimony is filtered and washed, rinsed into a beaker, the paper added, and treated with ferric sulphate, either solid or in solution, in the proportion of 6 molecules of the latter to 1 of the former. The mixture is boiled for fifteen minutes, the following reaction taking place:

$$Sb_2S_3 + 5Fe_2(SO_4)_3 + 8H_2O = 2H_3SbO_4 + 10FeSO_4 + 5H_2SO_4 + S_3.$$

After considerable dilution, 15 c.c. of strong sulphuric acid are introduced for every 1 gramme of ferric sulphate, the liquid is cooled below 25° C., and titrated with permanganate containing 1 or 1·5 gramme per litre. The error lies between +0·3 and −0·26 per cent. of the original sulphide of antimony. F. H. L.

A New Volumetric Method for Determining Copper. W. E. Garrigues. (*Jour. Amer. Chem. Soc.*, 1897, xix., 940, 941.)—This method depends on the precipitation of the copper as cuprous thiocyanate and the alkalimetric determination of the combined thiocyanic acid. The solution is evaporated with the smallest possible amount of sulphuric acid to expel any volatile acids, is then diluted, gently warmed, and sulphurous acid added until the liquid smells perceptibly of it. The copper is precipitated with an alkaline thiocyanate, the liquid gently warmed to promote the separation of the precipitate, and the latter filtered off and washed with water.

The filter and contents are then boiled for a few minutes with a measured excess of standard caustic alkali, the liquid cooled, made up to 200 c.c., filtered, and 100 c.c. titrated with standard acid and methyl orange.

The caustic alkali converts the cuprous thiocyanate into cuprous hydroxide and alkaline thiocyanate, the latter substance being neutral to methyl orange. The reaction is in accordance with the equation:

$$2CuSCN + 2NaOH = Cu_2(OH)_2 + 2NaSCN.$$

For the separation of zinc from copper, ammonium thiocyanate must be used to precipitate the copper, and the zinc determined as phosphate in the filtrate. When potassium thiocyanate is used, the zinc precipitate is contaminated and the results valueless.

The author claims for this process greater accuracy than the iodide method is capable of, and an additional advantage is that no empirical standard is required.

C. A. M.

The Electrolytic Determination of Cadmium. D. L. Wallace and E. F. Smith. (*Jour. Amer. Chem. Soc.*, 1897, xix., 870-873).—Avery and Dales (ANALYST, xxii., 295), being unable to obtain satisfactory results by Smith's method of precipitating the metal from an acetic acid solution, the authors have made experiments to determine the original working conditions, and find that when a definite strength of current is employed and a definite surface (which, however, were not given by Smith), the method is perfectly reliable. For instance, 0·1329 gramme of cadmium oxide was dissolved in acetic acid, the solution evaporated to dryness, and the residue dissolved in 30 c.c. of water. The liquid was then heated to 50° C., and electrolyzed with a current of 0·02 ampère for 37 sq. cm. of cathode surface, the voltage was 3·5. The metal, which was completely precipitated in four hours, was crystalline and perfectly adherent. The acid liquid was siphoned off and replaced by water without interrupting the current. It was found that the time required could be diminished and good results obtained by adding 1 gramme of ammonium acetate to

the solution after the current had acted for an hour. In this particular instance the quantity of cadmium found was 0·1158 gramme, instead of 0·1162 gramme.

Experiments are also described to show that, contrary to the experience of Avery and Dales, it is possible to obtain good results by precipitating from a solution containing free sulphuric acid if the right conditions obtain. Thus, 0·1270 gramme of cadmium oxide was dissolved in 2 c.c. of sulphuric acid (specific gravity, 1·09), and the solution diluted with water to 30 c.c. It was then heated to 50° C., and electrolyzed for four and a half hours with a current of 0·08 ampère for 37 sq. cm., cathode surface, the voltage being 2·5. The deposit was crystalline and adherent, and weighed 0·1105 gramme instead of 0·1111 gramme.

With regard to the electrolytic separation of cadmium from copper, Smith showed that in the presence of free nitric acid copper was deposited, whilst the cadmium remained in solution. But Heidenreich (*Ber.*, xxix., 1,585) could not obtain satisfactory results by this process. In reply to his criticism, the authors describe experiments, of which the following is representative: To a solution containing 0·3893 gramme of copper sulphate (= 0·0988 gramme copper) and 0·1152 gramme of cadmium oxide (= 0·0985 gramme cadmium) were added 2 c.c. of nitric acid (specific gravity, 1·43). The solution was diluted to 100 c.c., heated to 50° C., and electrolyzed with a current $N.D_{100} = 0·10$ ampère. Voltage, 2·5. The metal, which was completely precipitated in three hours, was bright and satisfactory in every respect. It weighed 0·0988 gramme, and contained no cadmium. C. A. M.

The Detection of Traces of Alkaline Carbonates in the Presence of Bicarbonates or Borax. A. Leys. (*Jour. Pharm. Chim.*, 1897, vi., 440-442.)—Salts of magnesium (*e.g.*, the sulphate) distinguish between alkaline carbonates and bicarbonates, giving a precipitate with the former and not with the latter. But the author shows that this reagent, though excellent with the single salts, is not to be relied on with mixtures. Thus, a solution of a mixture containing 68 per cent. of neutral carbonate and 32 per cent. of bicarbonate of soda gave no precipitate with magnesium sulphate, and the same negative result was obtained with a mixture consisting of 60 per cent. of neutral carbonate and 40 per cent. of borax.

A saturated solution of calcium sulphate forms a much more sensitive reagent. When this is added to a solution of pure bicarbonate the liquid remains clear for some time, and then slowly begins to form microscopic crystals, but if there be only a minute trace of neutral carbonate present, an immediate white opaque precipitate is formed. The test is equally reliable in the presence of borax. C. A. M.

Acidimetric or Alkalimetric Determinations in highly-coloured Substances. F. Jean. (*Ann. de Chim. Analyt.*, vol. ii., p. 445.)—The ordinary indicators being inapplicable in the case of highly-coloured products such as ink, blacking, etc., the author recommends the following method:

If the substance give an alkaline reaction, a weighed quantity is distilled with ammonium sulphate; and the quantity of the alkali, the nature of which has been previously determined by qualitative analysis, estimated by titrating the ammonia liberated.

Acid substances should be distilled in a Schloesing apparatus with ammonium sulphate and 10 c.c. to 20 c.c. of normal alkali, the ammonia liberated by the excess of alkali being absorbed by 10 c.c. or 20 c.c. of normal acid. The excess of the latter is then titrated. C. S.

Estimation of Total Carbonic Acid in Water. S. Robertson. (*Arch. Hyg.*, 1897, xxx., 312; through *Chem. Zeit. Rep.*, 1897, 268.)—According to the volume of carbon dioxide probably present, 10 to 20 c.c. of trinormal alcoholic soda (or potash), prepared from metal and absolute alcohol, are placed in a 600 c.c. flask of hard Jena glass, a rubber stopper is inserted in the neck, and the whole weighed. About 500 c.c. of the sample are next cautiously introduced through a leading tube in order to avoid contact with the air, and the exact amount of water taken is determined by a second weighing. The liquid is then distilled till only 100 c.c. are left in the flask, the exit tube for the vapours being provided with a bulb to prevent loss of solid matter by splashing. Finally, the vessel is connected with a series of drying tubes, hydrochloric acid is run in through a tube funnel, the carbonic acid driven out by gentle warming and a current of pure air, and absorbed in potash bulbs, where it is estimated by weight as usual.

The process can also be employed for the determination of the combined carbonic acid by omitting the caustic alkali. F. H. L.

Detection of Alkalinity in Potable Waters. A. Cavalli. (*Selmi*, 1897, vii., 65; through *Chem. Zeit. Rep.*, 1897, 288.)—An extremely sensitive reagent for this purpose is found in a 1 per cent. solution of tolylene red (dimethyldiamido-tolylphenazine hydrochloride). If two or three drops of this dye are added to 50 c.c. of an ordinary alkaline water, the red colour changes to yellow.

Alessandri has suggested the addition of a few drops of red wine, the colour of which is altered under similar conditions. F. H. L.

The Determination of Oxygen dissolved in Water. G. Romyn. (*Zeit. angew. Chem.*, 1897, 658.)—The author uses a cylindrical pipette with a tap at each end and a tube above the upper tap. The pipette is completely filled with the water to be examined and the taps closed. One c.c. of a solution containing 12 grammes of manganese chloride and 8·5 grammes of potassium iodide in 100 c.c. is placed in the upper tube and allowed to enter the pipette by momentarily opening both taps. The liquids are well mixed, and then 1 c.c. of a solution of Rochelle salt (specific gravity, 1·255) and 1 c.c. of soda lye (specific gravity, 1·105) introduced in the same way.

After leaving for ten minutes, 1 c.c. of hydrochloric acid (specific gravity, 1·126) is added, the pipette emptied into a flask, and the liberated iodine titrated with standard thiosulphate. The alkaline manganese tartrate combines with the dissolved oxygen, and on the subsequent addition of the hydrochloric acid liberates from the potassium iodide an amount of iodine equivalent to the oxygen. A deduction of 4 c.c. must be made from the volume of the pipette for the reagents introduced.

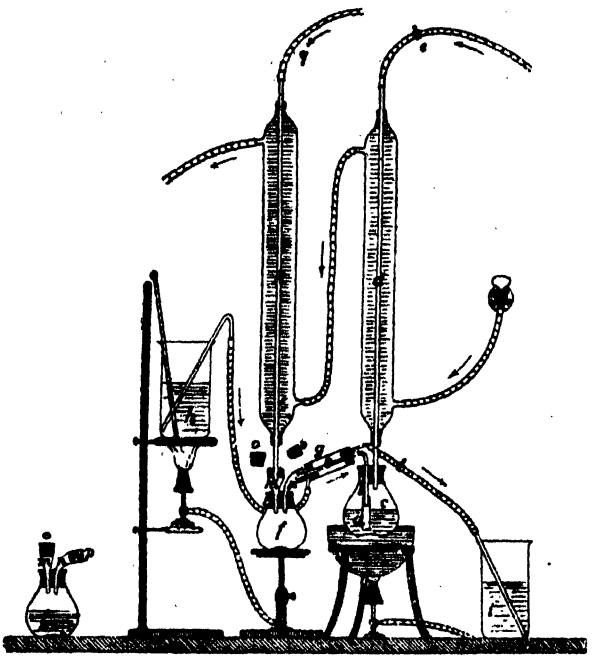
The pipette may be obtained from Greiner and Friedrichs, Stützerbach.

C. A. M.

Estimation of Potash in Fertilizers. L. Ronnet. (*Rev. Chim. Analyt. Appl.*, vol. v. [21], pp. 421, 422.)—To obviate the inconvenience arising from the use of ammonium carbonate for precipitating the excess of barium in the Schloesing perchloric method of estimating potash, the author proposes to throw down the barium by means of a current of carbon dioxide.

In the case of potassium chloride fertilizers, 50 grammes are dissolved in water, made up to 1 litre and filtered; 20 c.c. of this solution are then taken and treated with 10 c.c. of a saturated solution of barium hydroxide. A current of carbon dioxide passed through the liquid for a few minutes throws down the excess of barium; and, after boiling for a few moments to drive off the residual carbon dioxide and decompose any soluble bicarbonates formed, the liquid is filtered and treated by the perchloric acid method in the ordinary manner.

For potassium sulphate fertilizers 40 c.c. (and for Kainit 30 c.c.) of baryta water will be required, and the precipitate requires more careful washing.



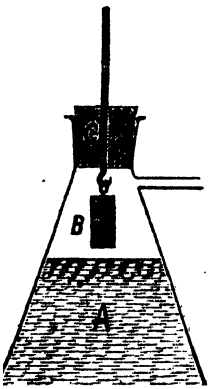
In the case of more complex fertilizers, 25 grammes are digested in hot water, and the volume made up to 500 c.c. After filtration 100 or 200 c.c.—according to the presumptive richness in potash—are evaporated to dryness in a porcelain capsule with 1 or 2 grammes of calcium hydrate, and ignited at a low temperature. The residue is taken up with small quantities of boiling water, and baryta water added so long as a precipitate continues to form. The excess of barium is thrown down, and the further treatment proceeded with as before. In all cases the liquid through which the carbon dioxide is passed should be well boiled afterwards.

C. S.

APPARATUS.

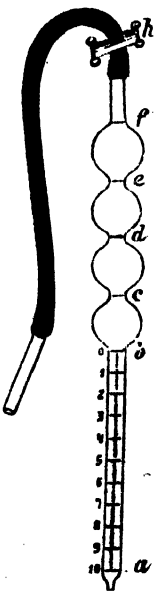
An Apparatus for determining the Solubility of Substances in Boiling Liquids. H. Göckel. (*Forsch. Ber.*, 1897., iv., 173-177.)—The usual method of determining the solubility of a substance in a boiling liquid (Fresenius, *Quant. Anal.*, ii., 794; Lassar Cohn, *Arbeitsmethoden*, 1893, 224) is to filter the boiling saturated solution through a warmed and covered funnel into a weighed flask, which is then closed with a stopper, allowed to cool, weighed, and the amount contained in an aliquot part of the liquid determined.

The author points out that in this process a considerable loss of the solvent by evaporation is inevitable, whilst the slightest cooling causes a separation of the dissolved substance on the funnel, and that these causes may lead to enormous discrepancies in the results obtained by different observers. Thus, according to Dragendorff, 1 gramme of theobromine requires for solution 422·5 grammes of boiling absolute alcohol, whereas Eminger found that 818 grammes were necessary.



In the apparatus here described, evaporation of the solvent during the filtration is impossible, and results in good agreement can be obtained. The substance and solvent are placed in the flask, *c*, which holds about 25c. c., and in which is also placed the filter-tube, *a*, which is filled with wool. The flask is heated for about thirty minutes on the water-bath, with *d* acting as a reflux condenser. Meanwhile, the liquid in the flask is kept in motion and prevented from entering the filter, *a*, by means of gentle air-pressure supplied by bellows connected with the condenser, *k*, at *q*. After the thirty minutes' boiling, the bellows are detached from the top of *k* and connected with the condenser, *d*, by means of the tube, *e*. On now gently blowing, the boiling saturated solution passes through the filter, *a*, and tube, *b*, and falls into the flask, *f*, where loss by evaporation is prevented by the condenser, *k*. In order to prevent crystallization in the tube, *b*, the latter is surrounded by a jacket, *g*, through which passes a current of warm water heated in the beaker, *h*, to a temperature of from 1° to 2° above that of the solvent. The tube, *b*, delivers into a wider tube, *n*, to which a stopper can subsequently be fitted, and a stopper is also provided for the tube, *m*, when disconnected from the condenser, *k*. The flask, *f*, with the tubes, whose combined weight when empty is known, is weighed when containing the saturated solution, and again after the evaporation of the solvent.

The results obtained by the ordinary method (as given by Fresenius), and those with the apparatus described above, are compared in the subjoined table, in which are shown the quantities of boiling solvents required to dissolve 1 gramme of caffeine.



Solvent.	Ordinary Method. Grammes of Solvent for 1 gramme Caffeine.	Mean.	With Apparatus described. Grammes of Solvent for 1 gramme Caffeine.	Mean.
Ether (anhydrous) B.P. 35·5° C. ...	434·6 474·4	454·5	336·8 341·8	339·3

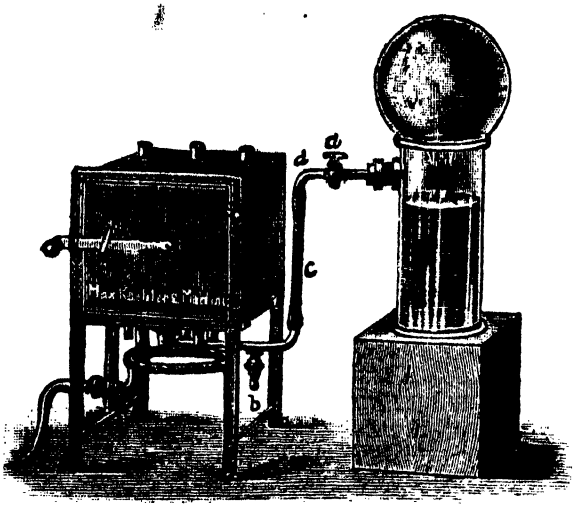
C. A. M.

Simple Hydrogen Apparatus. C. Aschmann. (*Chem. Zeit.*, 1897, xxi., 1049.)—This device is sufficiently explained by the diagram. A is a filter-pump flask holding about 1½ litres, two-thirds filled with dilute sulphuric acid. B is a solid block of zinc 6 cm. long and 2 cm. in diameter, cast round a copper wire with a loop at the top, by means of which it is suspended, as shown. The cylinder is pushed into or drawn out of the acid, according as a current of gas is required or not.

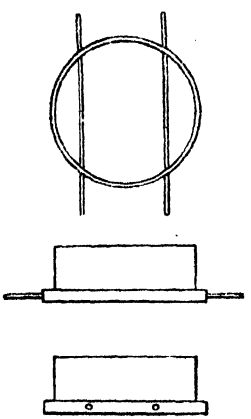
F. H. L.



A New Measuring Pipette. Otto Bleier. (*Chem. Zeit.*, 1897, 1028.)—By means of the comparatively short pipette, illustrated in the accompanying cut, any quantity of liquid up to 50 c.c. can be accurately measured. The instrument is divided into five sections, each of which has a capacity of 10 c.c., the lowermost being graduated in tenths of 1 c.c. The amount of liquid delivered is regulated by the screw clamp *h*. The constrictions between the bulbs have the same diameter as the graduated portion.

W. J. S.

Drying Oven for Maintaining Constant Temperatures. M. C. Schuyten. (*Chem. Zeit.*, 1897, xxi., 1049.)—This consists of a constant level apparatus placed in connection with an ordinary copper water-oven. When a temperature of 97·5° C. is required, both parts contain water, and the whole is worked in the usual way. But if a higher temperature (98° to 105°) is desired, the oven is filled with a strong solution of sodium nitrate, while the reservoir is charged with plain water as before. The wooden block is of such height that equi-



librium obtains when the drying-oven is practically full of liquid; the cock *a* is closed, the burner lighted, and as soon as ebullition sets in, *a* is opened. If a thermometer shows that the temperature is too low, more solid sodium nitrate is introduced through one of the openings in the oven; but if it is too high, *a* is shut, and some of the solution is drawn off from *b*. After a few trials, the proper concentration will be obtained; and then the temperature will remain steady, even if the gas-flame varies in size, so long as the liquid continues to boil; for the loss by evaporation is constantly made good by the addition of pure water.

Sodium nitrate seems best adapted for this purpose because it does not act appreciably on copper; but it must be very pure, and especially free from chlorides or sulphates.

F. H. L.

New Electrolytic Diaphragm. H. Pauli and L. Pincussohn. (*Chem. Zeit.*, 1897, xxi., 1048.)—The ordinary commercial porous pot is inconvenient for electrolytic analysis, as it is difficult to watch the process going on inside, and the outer electrode must be bent into a circular form. The improved cell recommended by the authors is made much shorter and wider, as will be seen in the accompanying illustrations. At its upper end it is strengthened by a flange in which four holes are bored; two wires are passed through them, and in this manner the cell is suspended within the outer vessel. The latter need not be a beaker; a flat crystallizing-pan is preferable. The electrodes are therefore not curved, but straight and parallel; and thus it is easier to maintain a uniform current density. The apparatus has been successfully employed in carrying out Weyl's process for the estimation of carbon in hard steels. F. H. L.

MISCELLANEOUS.

We are pleased to hear that the governing body of University College, Nottingham, has conferred the title of Emeritus Professor on Dr. Clowes on his retirement from the Professorship of Chemistry in the College to undertake the duties of Chemist to the London County Council.

THE ANALYST.

MARCH, 1898.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE annual meeting was held on Wednesday, February 2, 1898, in the Chemical Society's Rooms, Burlington House, the President (Dr. Bernard Dyer) occupying the chair.

The minutes of the previous meeting were read and confirmed.

The following gentlemen were proposed for election. As members: H. H. Dains, F.I.C., 3, Cantonment, Vizianagram, India; A. D. Hall, M.A., Principal of and Professor of Chemistry at the South-Eastern Agricultural College, Wye, near Ashford, Kent; Otto Rosenheim, Ph.D., 57, Chancery Lane, London; P. Schidrowitz, Ph.D., 57, Chancery Lane, London. As associates: C. A. Hackman, assistant to Mr. A. C. Chapman; and A. P. Davson, assistant to Mr. Bodmer. Mr. L. K. Boseley was elected a member of the Society, and Mr. F. R. O'Shaughnessy as associate.

The HON. TREASURER (Mr. E. W. Voelcker), in presenting his report and accounts for the past year, drew attention to the fact that, while the amount of the year's expenditure was larger than in the case of the previous year, the balance actually standing to the Society's credit was larger. He was glad to be able to remark that the subscription list was in a more satisfactory condition than it had been in since 1895, there being, as a matter of fact, only five subscriptions remaining in arrear; and he desired to express his appreciation of the kindness with which the members generally had responded to his applications. The chief items in the Society's expenditure were those connected with the ANALYST, and these items were larger than in the previous year, this being in great measure due to the cost of the General Index which had been published during the year just concluded, and of which the cost of printing alone had been £53. He might observe, however, that the items referring to the ANALYST constituted the only portion of the accounts which showed an increased expenditure over the preceding year, the Society having, in fact, been as economical as possible in every direction, excepting that which, he ventured to say, was the one in which they were right in being lavish in their expenditure. Any surplus money they had to spend, he thought they ought to spend in raising that journal to as high a standard as possible.

Mr. JOHN H. B. JENKINS moved the adoption of the report and accounts as

presented by the Hon. Treasurer, at the same time proposing a hearty vote of thanks to the Hon. Treasurer and to the Hon. Auditors (Mr. John Hughes and Mr. Bertram Blount).

Mr. EKINS seconded the motion, which was unanimously carried.

The HON. TREASURER and Mr. HUGHES responded, the latter saying that the accounts were kept with great accuracy of detail, and in such a clear and admirable manner that the task of auditing them was a very light one.

The President then delivered the following address.

ANNUAL ADDRESS OF THE PRESIDENT.

I REGRET to have to begin the remarks I have to make by chronicling the fact that we have lost by death during the past year four of our members. The first name among them is that of our honoured honorary member, Fresenius. His loss has been deplored all over the chemical world; but there is no chemical body or society to whom it comes home with such force as it does to a society which, like our own, is devoted specially to the study and advancement of analysis, the branch of chemical work to which Fresenius devoted his long and fruitful life. His well-known handbooks are among the earliest and best-used possessions of the student, and they are, at the same time, among the most treasured possessions of the most mature analyst among us. Our past-President, Mr. Hehner, who was privileged to be his pupil, has already recorded, much more ably and eloquently than I could, in the pages of our journal the appreciation necessarily felt by all analysts of the work of Fresenius and our sorrow at his death; but I nevertheless feel that it would not be becoming to let our annual meeting go by without once again recording our sense of the loss we have all sustained.

Mr. F. M. Rimmington, whose loss has also been chronicled in the ANALYST, was one of the oldest members of our Society, and, I think, one of the oldest public analysts in the country; and, although advancing years prevented his taking a very prominent part in the affairs of our Society for some time past, he was formerly active in analytical research, more especially in connection with the examination of drugs.

Dr. G. A. Rogers was also an old member of the Society, and an old public analyst, although he had not, I think, for many years taken any active part in our society.

Mr. C. H. R. Moore was for a number of years a member of the Society, and for several years previously an associate. He was originally one of my own pupils and assistants, and one for whom I had a deep personal attachment, and his early death has been, as I know, a subject of grief to a number of our members who knew him as a familiar friend before he left England. At the time of his death he was working at agricultural chemistry in Jamaica.

We have lost during the year by resignation two of our ordinary members, while the names of three members and one associate have fallen out of our list by reason of efflux of time since their last communication with our treasurer.

We have thus lost during the year one honorary member, eight ordinary members, and one associate. We have had, however, the pleasure of adding to our list of honorary members the name of Dr. W. J. Russell, F.R.S., who has earned the thanks of the whole profession for the able way in which for three years he filled the presidential chair of the Institute of Chemistry. Our appreciation of his services in this capacity cannot be better expressed than by saying that he proved himself a worthy successor to Dr. Tilden, with whose name will always be associated what I venture to call the rejuvenescence of the Institute of Chemistry; and we have recorded our sense of Dr. Russell's services to our profession in the same way as that in which we recorded our recognition of those of his predecessor, Dr. Tilden.

This would perhaps be a fitting place to congratulate both our own Society and the Institute of Chemistry upon the fact that Dr. Russell, in resigning his office, has been succeeded by a President no less worthy than our own immediate past-President, Dr. Stevenson, whose hard work in the chair of this Society will be long remembered by all those of us who had to work with him in an official capacity. Under his presidency, we hope to see the Institute holding, in addition to its other examinations, an examination in the much-vexed subject of pharmacology and therapeutics, so as to enable candidates for public analystships to produce evidence of the supplementary qualification in this subject required by the Local Government Board, and thus removing a difficulty frequently experienced. We as chemists have long striven to impress upon the Local Government Board the urgent necessity of a strong chemical qualification for public analysts; but from the unfortunate frequency with which in the past the Local Government Board has expressed itself satisfied with the qualifications of candidates possessed of medical diplomas, but possessed of very slender chemical qualifications, it would almost appear as though in the eyes of the Local Government Board a therapeutical qualification had sometimes weighed even more heavily than a chemical one. If the Institute of Chemistry is able to see its way, as we now hope that it will, to supplement its already sound and thorough chemical examinations by the pharmacological and therapeutical examination already referred to, it will form a completely qualifying body for the special department of the profession which this Society primarily represents.

At one time, in view of the absence anywhere of any examination sufficiently comprehensive and at the same time sufficiently special to test the qualifications of candidates for public analystships, there was on the part of many members of our own Society a wish that we—the Society of Public Analysts—should examine, and grant a diploma. Others of us, however, felt that to further increase the number of examining bodies was exceedingly undesirable, and that this important work was one best reserved for the Institute of Chemistry, which, by its objects, its charter, and its organization, was eminently fitted for carrying out this, among other special as well as general examinations; and it is satisfactory now to know that such an end to the discussion seems likely to be happily brought about.

We have elected during the year ten new ordinary members, while three associates have been transferred to the rank of members. One member who had formally resigned has cancelled his resignation, and four new associates have been added to our list.

The strength of the Society, as compared with its strength at the close of the two preceding years, is as follows:

	January, 1896.	January, 1897.	January, 1898.
Honorary members	10	11	11
Members	210	218	223
Associates	26	29	31
Total	246	258	265

It will be seen that during the past year we have on the whole gained five members and two associates, as compared with a gain of eight members and three associates in the preceding year. Although, however, the Society will be seen to be growing, the growth is too small to be looked upon as satisfactory, having regard to the large enterprise we have held in hand since we enlarged the scope of our journal. I would ask our members to bear in mind that, although our title is a restricted one, our membership is open to any chemist who has the responsible conduct of an analytical laboratory, and I sincerely hope that any member of the Society who has friends who are eligible for our membership, and who are still outside our ranks, will at once impress upon them that to support the only journal in the English language devoted to a comprehensive record of the progress of analytical chemistry is the duty of every member of the profession; and that that support is best given by joining our Society.

While, however, I am very earnest in this appeal, I do not wish it to go out as a presidential utterance that we are in actual or immediate need of funds. During our earlier and less ambitious years we accumulated, for a young Society, a not inconsiderable amount of funded property. During the year that has just passed we have not had to trench upon our investments, but I regret to say that we have not been able to add to them. From the treasurer's statement you will see, indeed, that our income has increased, but you will see as well that our expenses have also increased materially, and it is scarcely necessary to remind you that the great bulk of our income is expended on our journal.

Of the activity of our Editorial Committee, and more especially of our able and energetic Editor, Dr. Sykes, I need scarcely remind you; but I should like to emphasize our work statistically by pointing out that during the year, in addition to 36 original papers, we have published in the pages of the ANALYST no less than 283 abstracts. My predecessor, Dr. Stevenson, was last year at the pains of tabulating the abstracts which we published during 1896, and in order to show the growth of this work I have made a similar analysis of the abstracts published during 1897, which I now give side by side with his.

	Abstracts published in the ANALYST. 1896.	1897.
Food and drug analysis	55	86
Toxicological analysis	9	5
Organic	86	87
Inorganic	86	91
Apparatus	9	14
Total	245	283

It will be seen, therefore, that our abstracts were 38 more than in the previous year. We endeavour, as far as possible, to abstract every paper of analytical importance published in any country and in any language, and we are anxious—I speak for the moment on behalf of the Editorial Committee—to make our journal still worthier of the Society; and in order to do this we want two things. As I have already said, we want an enlargement of the membership of the Society, and we want an increase in the number of original papers read before the Society. During the past year 34 papers have been read and discussed at our monthly meetings, as against 29 during the previous year; but I should like to see a much larger record than this, and I should like to see a wider range of analytical subjects. I am afraid that many chemists read or publish elsewhere papers that ought properly to be read and discussed at our meetings, on account of our name, which leads them to suppose that the only papers acceptable here are those having to do with subjects falling within the statutory duties of public analysts as such. There cannot be a greater mistake. Even those among us who are primarily public analysts, are, for the most part, in general practice, and are interested, individually or collectively, in the widest possible range of analytical subjects, and any paper on any subject whatsoever connected with analytical chemistry is heartily welcomed at the meetings of our Society. I say this, not for the information of those who are present, but for the sake of others who are not members of our Society, under whose eyes this address may fall, for I am glad to say that the ANALYST has a large chemical reading public outside of our Society, and it is in the ranks of that chemical reading public that I would fain find more contributors of papers and more recruits for the Society itself.

I do not wish, however, on behalf of the Council and officers of the Society, to appear to be in any way ungrateful for the 34 papers read before us during the year, many of which have been most interesting and most valuable to us, and of which the following is a list:

"Note on weighing out Fats." By Charles E. Cassal.
"A Specific Gravity Pipette." By W. F. Keating Stock.
"A modified Schmidt Process." By R. W. Woosnam.
"Some Analyses of Water from an Oyster Fishery." By Charles E. Cassal.
"The Composition of Meat-extracts and similar Products." By Otto Hehner.
"Remarks on Formaldehyde." By Charles E. Cassal.
"The Distillation of Formaldehyde from Aqueous Solution." By Norman Leonard, B.Sc., Harry M. Smith, and H. Droop Richmond.
"The Estimation of Milk-sugar in Milk." By H. Droop Richmond and L. K. Boseley.
"The Constitution of Milk." By H. Droop Richmond.
"Copper in Preserved Vegetables." By R. Bodmer and C. G. Moor, M.A.
"Coffee Palace Coffee Infusions." By E. G. Clayton.
"The Detection of Mixtures of Diluted, Condensed, or Sterilized Milk with Fresh Milk." By H. Droop Richmond and L. K. Boseley.
"The Separation and Identification of the Typhoid and Colon Bacilli." By F. Wallis Stoddart.

"Notes on Alcohol." By J. F. Liverseege.

"The Value of the Nitrogen Factor in the Analysis of Decomposed Milks." By Alfred Smetham.

"Notes on the Influence of Boric Acid upon the Action of Digestive Ferments." By R. A. Cripps.

"Note on Heavy Metals in Cheese." By Alfred H. Allen and F. Hudson Cox.

"On the Structure of the Fat Globules in Cows' Milk." By Professor V. Storch, of Copenhagen (communicated by H. Faber).

"On Tabarie's Method for the Estimation of Alcohol." By Norman Leonard, B.Sc., and Harry M. Smith.

"The Determination of Soluble Proteids by Chlorine Precipitation." By S. Rideal, D.Sc., and C. J. Stewart.

"Note on the Bacteriolysis of Gelatin." By S. Rideal, D.Sc., and R. Orchard.

"Note on Commercial Ground Cassia." By W. F. Keating Stock.

"An Improved Method of Determining Proteid and Gelatinoid Substances." By Alfred H. Allen and A. B. Searle.

"The Estimation of Acetates in the Presence of Inorganic Salts." By Bertram Blount.

"The Estimation of Carbonic Acid in Natural Waters." By Clarence A. Seyler, B.Sc.

"Note on the Graduation of Leffmann-Beam Bottles." By G. E. Scott-Smith and A. B. Searle.

"The Detection of Gelatin in Cream." By Alfred W. Stokes.

"A new Milk Preservative." By Alfred W. Stokes.

"A new Milk Adulterant." By Alfred W. Stokes.

"An improved Milk Scale." By H. Droop Richmond.

"Milk Analysis and Certification." By James Edmunds, M.D.

"A Butter eighteen years old." By E. G. Clayton.

"A Method of Estimating Tannic Acid by means of the Polarimeter." By R. F. Wood-Smith.

"Note on Mineral Matter in Commercial Bleached Ginger." By E. J. Bevan.

As all, or nearly all, of these papers have been actually published in the ANALYST, I need not now linger to review them, but I should like to refer especially to two among them. The first was a paper "On the Separation and Identification of the Typhoid and Colon Bacilli," by Mr. Stoddart. It is gratifying to us as analysts that this, one of the most interesting papers published upon a most important and interesting topic, should have been the work of one of our own members, and a "working public analyst." I am convinced that those of us who undertake the analysis of water—and what analyst does not?—will ultimately have one and all to adopt bacteriological methods as supplementary to our chemical analyses, if we are determined to place ourselves in possession of the fullest possible evidence to be obtained from the samples of water submitted to us. But it must be recognised that bacteriological science is not the all-powerful thing that the unscientifically educated public is apt for the time being to suppose. Its difficulties have nowhere been better demonstrated than by Mr. Stoddart in this room, when he showed us how complex

was even the single group of organisms usually associated together under the common designation of the *Bacillus coli communis* group. The separation and identification of the typhoid organism by the really beautiful methods demonstrated by Mr. Stoddart and its differentiation from its innocent cousins, is no doubt under some circumstances possible, but it appears to be very doubtful whether these circumstances are the ordinary everyday circumstances under which the water analyst is called upon to act. What has occurred with reference to the terrible epidemic at Maidstone will act as a wholesome check to those who have cried out that bacteriology is everything, and that the bacteriologist is destined to supersede the chemical water analyst. In Maidstone we have had one of the most severe epidemics of modern times, clearly traced, as far as circumstantial evidence can possibly go, to a particular portion of the public water-supply. Our past-President, Dr. Adams, as Medical Officer and Public Analyst for Maidstone, was charged with the duty of investigating this source of supply, and his analyses have given clear indications of undesirable contamination. But Dr. Adams has had associated with him in the inquiry one of our ablest bacteriologists, Dr. Washbourn, of Guy's Hospital, who had before him what, from the bacteriologist's point of view, must be regarded as a magnificent opportunity for demonstrating the value of bacteriology as a means of indicating specific infection. What has been the result? Dr. Washbourn, after a most exhaustive examination, has been unable to separate or identify the typhoid bacillus in the very water which, with more than mere presumption, may be said to have been distributing the disease-germs which he sought to find. Not only has Dr. Washbourn been unable to detect the typhoid bacillus, but he expresses his doubts as to whether in any of the earlier cases in which it is said to have been identified in connection with the dissemination of disease by water, the bacillus has really been discovered, its reputed discovery having been made when bacteriological methods were less precise than they are now, and when, I may add, it was easier to jump to rash conclusions. In fact, although the typhoid bacillus may now be capable of satisfactory identification when once we can grow a colony of it, the difficulty of growing, or rather of lighting upon a colony, among the overwhelming progeny of concomitant organisms of the *Coli communis* group is so remote as to be, as Dr. Washbourn seems to recognise, almost outside the field of practical laboratory work.

But Dr. Washbourn's bacteriological examination must not, however, on this account be said to have been a failure. He has shown that in many cases the bacteriological condition of the water, while it has not sufficed to demonstrate specific infection, has sufficed to demonstrate fæcal pollution in certain sources of the water-supply, thus giving independent confirmation of the chemical results of Dr. Adams.

I will not say more about Maidstone, because I have asked Dr. Adams to come here and tell us, from the analytical point of view, the story of his work in connection with the epidemic, and I hope that at an early meeting he may be able to do so. But before leaving the subject, I would again say that, although I look forward with very little confidence to bacteriology as a practical means of identifying the typhoid bacillus under the ordinary circumstances of the spread of the disease by polluted water, I must repeat that I have the greatest possible faith in the value of bacteriology

as an adjunct to the chemical analysis of water. For some years now I have made bacteriological cultures in every water sent to me for analysis, ascertaining the number of colonies per volume capable of growth on gelatin at the ordinary temperature, the number of colonies growable on agar at blood heat, and the number growable on acidified phenolized agar at the same temperature. Any analyst who will systematically do this side by side with his chemical analysis, and steadily compare the results, will after a time feel himself very greatly strengthened in pronouncing his opinion on the great majority of cases that come before him. Occasionally anomalous cases occur, and it is obvious that the origin of a water greatly affects the opinion to be arrived at; but the same thing is true of many of the chemical features of a water analysis. I think that any water analyst who has once systematically habituated himself to make such a bacteriological examination as that indicated would feel his judgment sadly lamed if he had for any reason to give up the practice, and to fall back upon his chemical results alone. I think, however, that the idea that the practice of such elementary bacteriology as is needed for practical purposes in the analysis of water requires for its understanding or accomplishment medical training or medical experience, or that the medical bacteriologist can find out something about a water which is beyond the powers of the ordinary public analyst who has learned simple bacteriological manipulation, has received its death-blow at Maidstone. Bacteriological examination of drinking-water is destined to become as everyday an operation as the determination of chlorides; but it is an operation that we can perfectly well undertake ourselves, and if we would recognise this, and learn to do it, our County Councils and local authorities will not think it necessary to hand over such work, which should properly be ours, to our medical brethren.

The other paper that I would single out for reference is that of Professor V. Storch, communicated to us last summer by our member, Mr. Harald Faber. I refer to this paper because it claims—and I do not think the claim, although disputed, has been set aside—to settle the long-debated question as to whether the fat-globules in milk are or are not surrounded by a special pellicle. Professor Storch, after a great deal of work, concludes that the pellicle after all exists, and, furthermore, that it consists of a special and hitherto unrecognised proteid body.

Among what may be called the domestic incidents in our Society, we have had to chronicle during the year a very pleasant country meeting, held at Derby, under the hospitable auspices of Mr. Archbutt and Mr. White, when we had the pleasure of visiting the Midland Railway Works, the Crown Derby Porcelain Works, and the very interesting printing and lithographic works of Messrs. Bemrose and Sons.

My predecessor, speaking from this chair a year ago, concluded his address with a devout hope that the Government would during the year introduce into Parliament a Bill based on the report of the Select Committee of the House of Commons on Food Products Adulteration, and that that Bill might not be crowded out by the plethora of less important matters. A part of that hope—viz., the introduction into Parliament of a Bill—was realized. You know already, however, that no Bill was introduced till the very end of the session, and then only as a mere formality; and you know also how fragmentary and incomplete was the Bill which the President

and Secretary of the Local Government Board then produced. This Bill has been the subject of very anxious and careful deliberation on the part of your Council, and as a result of that deliberation a report has been issued, fully pointing out the directions in which the Bill should be amended in order to give substantial effect to the recommendations of the Select Committee. This report has been placed before the Local Government Board, and is being issued to all public authorities interested in the carrying out of the Food Acts, as well as to all members of Parliament. As a copy of the report has been placed in the hands of every member of the Society, and as it has been fully published in the ANALYST, and as, furthermore, the subject was discussed at some length by Mr. Kearley, M.P., at our recent annual dinner, I need not take up your time now by discussing it further. Suffice it to say that we were all severely disappointed by the Government Bill; and that we hope that after all it may not have been the final intention of the Government to stop short at the very insufficient alterations in the law therein proposed, but that we may in the coming session be gladdened by the production of a fresh Bill, which shall, as I have said, substantially give effect to the recommendations of the Select Committee of the House of Commons, more especially with regard to the appointment of that Standing Committee of Reference, which is indispensable for dealing with the many vexed questions calling for settlement which cannot themselves be dealt with in a single Act of Parliament, however comprehensive.

In concluding these somewhat desultory observations, I have, as your President, to acknowledge the heavy and untiring work performed by our officers—the honorary secretaries and the honorary treasurer. The year has been, owing to the important matters which we have had to consider, a toilsome one for our secretaries, and I am afraid that I cannot promise them much rest in the year that is to come; but I am sure their hearts are so fully in the multifarious work we shall have to get through, that the harder it becomes the more satisfied they will be.

Mr. JOHN HUGHES, in proposing a vote of thanks to the President for his address, desired to make one remark on the subject of the extension of the Society. The President thought, and rightly, that they should look to an increased number of members as a means of increased revenue; and, while agreeing in this, he would venture to suggest that as the journal became more valuable, its price should be increased to those outside of the Society. He thought that if it were made more expensive to obtain the journal without joining the Society, the result would be an increase in membership. As it was, many persons obtained the advantages of the journal without being members of the Society. With regard to what the President had said with reference to the Institute of Chemistry in his address, he (Mr. Hughes) was not inclined to agree with the resolution which had been passed by the Institute Council, but he had not been able to be present at the last Council meeting. He did not see why the Institute should be called upon to furnish authority as to qualification in therapeutics; he thought that what the Institute had to do was to give qualification in chemistry, and he did not see how it could give to chemists a qualification which many of its members themselves did not possess, or who the examiners were to be. He would have much preferred that the action should have been left to some other society—at all events, for the present; but he had no doubt that the Council of the

Institute had gone into the question very much more fully than he himself had been able to do, and that they had been enabled to come to a right conclusion. Their own President had himself held at first somewhat different views on the question, and other members also had altered their views upon considering and inquiring into the matter, and he had no doubt that there were very good reasons for the passing of the resolution. Referring again to the accounts, he certainly thought that the sums derived from life membership subscriptions should be funded in future, because they represented compositions of possible future payments.

The motion was seconded by Mr. PERCY A. E. RICHARDS, and carried unanimously.

The PRESIDENT said that he was pleased that Mr. Hughes thought that possibly, after all, the Council of the Institute of Chemistry had come to a correct conclusion in the matter of therapeutical qualification. He certainly thought that the best thing was that all necessary examinations should be held by the Institute of Chemistry, and there would surely be no difficulty in finding proper examiners in the new subject. That, however, was not a meeting of the Institute of Chemistry, but of the Society of Public Analysts; but the matter was so important a one, as affecting the particular branch of the profession in which so many members of the Society were engaged, that he had thought it right to take that opportunity of drawing attention to it. He now had to propose a vote of thanks to the President and Council of the Chemical Society for allowing the Society for another year to have the use of their rooms. If there were not some other society who would open its doors in this manner to them, the Society of Public Analysts would not be in such a good financial position as it then was, for it would be taxed with heavy expenses for rental. He therefore had pleasure in moving from the chair that the cordial thanks of the Society of Public Analysts should be given to the President and Council of the Chemical Society for the use of their rooms during the past year.

The motion was carried unanimously.

The following papers were then read:

"Copper 'pure for analysis.'" By J. W. Westmoreland.

"Note on the tests for distinguishing boiled from unboiled milk." By H. Leffmann, M.D.

The following is a list of the officers and Council elected for 1898:

President.—Bernard Dyer, D.Sc.

Vice-Presidents (who have filled the office of President).—M. A. Adams, F.R.C.S.; A. H. Allen; Sir Chas. A. Cameron, M.D., F.R.C.S.; A. Dupré, Ph.D., F.R.S.; Otto Hehner; Alfred Hill, M.D., F.R.S.E.; J. Muter, M.A., Ph.D., F.R.S.E.; Thos. Stevenson, M.D., F.R.C.P.

Vice-Presidents (who have not filled the office of President).—A. P. Aitken, D.Sc., F.R.S.E.; W. W. Fisher, M.A.; J. A. R. Newlands.

Hon. Treasurer.—E. W. Voelcker, A.R.S.M.

Hon. Secretaries.—E. J. Bevan; Charles E. Cassal.

Other Members of Council.—Bertram Blount, A. Wynter Blyth, M.R.C.S., R. Bodmer, A. C. Chapman, Sidney Harvey, C. G. Moor, M.A., S. Rideal, D.Sc., J. E. Stead, F. Wallis Stoddart, Walter J. Sykes, M.D., J. A. Voelcker, M.A., B.Sc., Ph.D., John White, W. C. Young.

THE ANNUAL DINNER OF THE SOCIETY OF PUBLIC ANALYSTS.

THIS was held on Tuesday evening, January 18, at the Criterion, under the chairmanship of the President, Dr. Bernard Dyer. About sixty-five members and guests were present, amongst the latter being Mr. Hudson E. Kearley, M.P., Dr. Thos. Stevenson (President of the Institute of Chemistry), Professor Frank Clowes, D.Sc. (President of the Society of Chemical Industry), Dr. Seaton (President of the Society of Medical Officers of Health), Mr. Walter Hills (President of the Pharmaceutical Society), Professor W. A. Tilden, D.Sc., F.R.S., Professor Armstrong, F.R.S., Mr. C. E. Groves, F.R.S., Professor Dunstan, F.R.S., Dr. Pakes, Dr. Messel, Mr. Fred. W. Beck, Mr. Aubrey W. Rake, Mr. G. C. Barnes, Mr. H. Owen, and Mr. J. F. Owen. The Chairman of the London County Council (Dr. W. J. Collins), who was to have proposed the toast of "The Society," was prevented from being present owing to the funeral of his colleague, Mr. Ashley Ponsonby.

The toast of "The Queen" having been duly honoured,

The CHAIRMAN proposed "The Houses of Parliament." He said that when he had the honour, a year ago, of proposing the same toast, he was buoyed up with the hope, as most of them were, that before his year of office had expired Her Majesty's Government would have produced a Bill which would have enabled Parliament to earn their thanks and congratulations for having placed upon the Statute Book an Act substantially giving effect to the recommendations of the Select Committee of the House of Commons on Food Products Adulteration. That hope, as far as the past year at all events was concerned, was doomed to disappointment. The first shock was received when, at the opening of Parliament, they read the report of the Queen's Speech, and saw with sorrow that there was no mention in that Speech of new food legislation. Their good friend Mr. Kearley (applause) made a gallant attempt to stimulate the Government into action by himself producing a very excellent Bill (hear, hear), a Bill which might very well, with perhaps a few alterations, have been adopted by Her Majesty's Government with a considerable saving of time and trouble to that Department, which Mr. Chaplin had lately told his constituents was so sadly overworked. While Mr. Kearley's stimulant was not altogether without effect, it had, however, to act on a constitution that was not very acutely responsive to stimulants, and its action was feeble. It resulted in the production, by the President of the Local Government Board, at the end of the session, of a short Bill which was exceedingly disappointing (hear, hear). The saddest feature, perhaps, about that Bill was the signature on the back of it of Mr. T. W. Russell, the Parliamentary Secretary of the Local Government Board, who had sat as Chairman of the Food Products Adulteration Committee, and who with his own hand had drafted most of the recommendations of which the very Bill of which he was obliged to stand sponsor took no notice. There was only one ray of hope in connection with the whole matter, and that was the statement made by Mr. Chaplin when he withdrew the Bill simultaneously with its introduction, a statement that he invited expressions of public opinion on the matter. It was to be hoped that even by that time public opinion had been expressed sufficiently strongly to assure the

President of the Local Government Board that the small measure which he introduced satisfied not a single one of the many interests affected by food legislation. The Bill, such as it was, had been so recently dissected and discussed by the Council of the Society of Public Analysts, whose report had been circulated among the members of the Society, that he did not propose then to refer to any of its details. The report of the Select Committee was throughout pitched in a very strong and very clear key, and its dominant note all through was the necessity for the appointment of a Standing Departmental Committee, or Court of Reference, which should deal with matters which could not possibly be dealt with completely in one comprehensive Act of Parliament. Public Analysts, as executive officers under the Sale of Food and Drugs Act, knew perhaps better than most people how urgent was the necessity for the formation of such a committee, if new legislation was to have any real effect for good on the food-supply of the country. The question, although a Parliamentary one, was not in any sense a party question. They were on the eve of a new session, and were hoping that Mr. Chaplin might introduce a Bill which should at any rate be some improvement on the one which he introduced a few months ago, and they hoped and trusted, and knew, that when that Bill was introduced their friend Mr. Kearley and those who thought with him in the House of Commons, no matter whether they sat on the one side of the House or on the other, would bind themselves firmly together to meet the necessities of the case, and to see that that Bill, if it required amendment, should be satisfactorily amended; and they hoped that the efforts of those friends would finally result in securing a satisfactory Act, which for many years to come should put an end to the many points on which so much burning discussion had arisen within the last few years. Mr. Kearley not only represented an important constituency of the British public, but he also, in his own person, represented the great mercantile interests of this country, and he was able to deal with this matter with a knowledge which was denied to many of those who sat with him in the House of Commons. Mr. Kearley had thrown himself for many years past with very great energy into this question, and they as Public Analysts, who wanted to do their duty better than they were able to do it at present, were grateful to him for the help that he had given to them in the past, and would give to them in the future; and he (the Chairman) would ask them, in drinking to the Houses of Parliament, to drink with that toast especially the health of their good friend and honorary member of the Society, Mr. Kearley (applause).

Mr. Hudson E. Kearley, M.P., said that he felt it an honour to have his name associated with that toast. The Chairman, in introducing it, had struck a note which appealed to him at once, in saying that at all events there was one question which had no party bearing, and that was the great question in which Public Analysts were so much interested. He was glad to be able to subscribe to that, and to go further and say that, in connection with the life of a member of Parliament, there was plenty of work to be done outside the limits of pure party obligations (hear, hear); and if there were pleasures that fell to the lot of members of Parliament, he would say that the most cherished were those that came from taking part in work that at all events contributed something towards the public advantage and welfare, and was not limited and confined as party work pure and simple naturally was. He

was sure that the company on that occasion were more interested in this particular question of food-products adulteration than in any other question, and therefore he would trespass on their attention by making some observations as to the course which legislation attempted to take during the last session, and as to the prospects that it might have during the forthcoming one. The Chairman had referred to the considerable disappointment experienced on all hands by the inadequacy of the legislation proposed in Mr. Chaplin's Bill. That Bill was a remarkable one, in so far as it was introduced at the expiry of the session merely in fulfilment of a pledge that a Bill should be introduced. No one within the walls of Parliament thought for a single moment that the Bill was intended seriously. Mr. Chaplin himself, indeed, rather described it as a *ballon en l'air*, and evidently expected that during the Parliamentary recess his abortive Bill would be torn to pieces, with the object of inducing him to introduce a more satisfactory measure. There would be plenty of criticism as to the direction which Mr. Chaplin should take in the coming session in bringing about a more perfect measure. The Bill introduced at the close of the last session simply, in his (Mr. Kearley's) opinion, trifled with a great national question. All the way along there had been ample evidence of technical and scientific difficulties which rendered it impossible for the present statutes to be effectual. A magistrate in a case was, perhaps, called upon to decide a technical question—it might be as to the percentage of borax that should be permitted in butter. One of their friends might come and declare that 0·5 was a perfectly safe percentage of borax to be introduced, while some more energetic gentleman might declare that 0·7 per cent. was a safe quantity, while the trembling criminal in the dock did not know what a borate was, and the gentleman on the bench probably did not know either, yet he gave a verdict, and fined the man forty shillings. All this had been impressed upon the Select Committee in the valuable evidence that they had been permitted to hear during three sessions, and the conviction grew in their minds that, as such questions were of a scientific and technical nature, it necessarily followed that they must have a scientific Board of Reference to whom these questions should be referred (hear, hear). The Select Committee differed very much among themselves upon certain other details: some of their agricultural friends, for instance, were, figuratively speaking, for hanging all margarine manufacturers, or preventing them from coloring their productions; but they all agreed with perfect unanimity that to deal with these scientific questions it was absolutely necessary that there should be constituted this Board or Court of Reference (hear, hear). But Mr. Chaplin in his Bill altogether ignored this strong and unanimous recommendation of the Select Committee, which was supported by the opinion of all the public bodies that came before them. The Corporations of Glasgow and other important towns sent competent gentlemen to give evidence, who supported the requirement of this Court of Reference. The merchants who came before them also supported it, and the retailer for his own protection demanded it. Even the agriculturists agreed, while analysts of course assented; and, above all, the Government officials themselves agreed. It was, however, ignored altogether, and he could not satisfy his mind as to the cause of its being so ignored, unless it arose from the fact that the Government had altogether a misconception of

the grounds of this great question. He rather imagined that they thought that the pressure which was being brought to bear upon them in Parliament was instigated by the agriculturists in the House of Commons, and he expected that each party was rather suspicious of its agricultural adherents. The agriculturists had certainly made some extreme proposals, and he could not help thinking that the Government might have thought it was the agriculturists who were pushing the movement forward. He said that advisedly, because Mr. Balfour, replying to a question which he (Mr. Kearley) had recently put to him in the House of Commons, had said that it was a very controversial question, and one which raised serious differences between town and country; and he rather imagined that that gentleman also shared the belief that the country people were trying to "run a racket" of their own to the detriment of the towns. Now he (Mr. Kearley) spoke as a townsman, and his views arose from his knowledge of the iniquity of the adulteration that went on unchecked in every town. It was not merely in towns, but in the poorest parts of towns, that adulteration was carried on to the greatest extent. London at that very moment was overwhelmingly full of adulteration, and it was the poor of the Metropolis and the other great centres of England who were the greatest sufferers. He desired himself, if he could, to dissipate the idea that this was a purely agricultural question. It was one which affected the towns more vitally than it did the agricultural districts of the country. So bad had adulteration now become, and so ineffectual had been the operations of local bodies to check it, that it had become necessary for those who were deeply interested in the subject to establish, as it were, their own police. There was in London what was known as the Butter Association, who were running to earth week by week some of these fraudulent gangs. In Lancashire the Agricultural Association had appointed its own inspectors, and was doing good work. According to their report they had taken last year 277 samples, of which no less a number than 135 were adulterated. That was a very serious amount of evidence as to the adulteration that existed. He was sure, from very intimate knowledge of the effects of such unchecked adulteration, that its continuance would ultimately sap the commercial honesty of the country. It was becoming a species of competition. Mr. John Bright, some forty years ago, had described adulteration as a form of competition, which might have been perfectly true in those days; but he (Mr. Kearley) would describe it as a form of robbery, and of the most gross and flagrant character (hear, hear); and the man who was subjected to such competition—if it were called competition, was perfectly entitled to claim the protection of the law. A man who put 30 per cent. of water into milk was a far greater criminal than any poor and starving man who committed a petty theft, although the latter would no doubt receive the heavier punishment. Those who practised adulteration battened and fattened on it, simply because the penalties that were inflicted upon them were quite inadequate to the amount of crime they committed (applause). He would not go further into the details of the abortive Bill that had been introduced by Mr. Chaplin, but he did feel it a pleasure to have the opportunity of supporting before Parliament the cause advocated by the Society of Public Analysts. He had had the honour on two occasions to move an amendment to the Address at the opening of Parliament, and he would look forward to the Queen's Speech with just the same

amount of interest on this occasion as he had done in preceding years. He hoped that there would be found a direct reference in that Speech to the determination of the Government to introduce a Bill, and if there was not, he should feel it his duty to again move an amendment to the Address, and it would be his endeavour and intention, all through the session upon which they were about to enter, to induce the Government, in the interests of Public Analysts, in the interests of consumers, and in the interests of distributors, to bring in a Bill that would be satisfactory to all those who were concerned, and he hoped that if he had the honour to be with the Society again next year, he would be in a position to congratulate them on the success of their endeavours (applause).

Professor TILDEN said that he had accepted with great pleasure the invitation to propose the toast of "The Institute of Chemistry," because, as he thought was well known, he had been very much interested in watching the progress of the Institute during many years. The Institute of Chemistry was established at a time when there did not exist in England any Society or Institute which was prepared to test the qualifications of chemists, and he used this term "chemist" advisedly, notwithstanding that he had had the advantage of sitting during the evening next to his friend, the President of the Pharmaceutical Society. It was well known, of course, that the Pharmaceutical Society, always forward in the field, had some forty years ago got a Parliamentary stamp put upon the type of chemists which it represented, and claimed patent rights in respect of this title. However, he thought he might venture to claim that he was on very good terms with his friend, whom, he had no doubt, the company would find desirous of being on good terms with them. The Chemical Society, which of course was an old Society, having long ago celebrated its jubilee, was approached more than twenty years ago on this question, and it was asked whether a department of the Society could be established, the object of which should be to inquire into the professional qualifications of young chemists, and to put upon them a kind of stamp which would be intelligible to the public. The Chemical Society did not at that time see its way to doing anything of this kind, and so, in 1877, the Institute of Chemistry was established. It went on for a few years, until in 1885 it received a Royal Charter, which for some time, as far as he could remember, did not seem to quite agree with it. A few years later it fell to his lot to offer certain advice, which he thought did it some good, although occasionally the advice that he ventured to offer had been received with rather a wry face. He said that not because he wanted to claim any credit in the matter, but because he wanted to suggest to the Institute that it must take another step or two in order to reach that position which all its fellows and all its well-wishers desired it to occupy. There had been a great deal of talk about its occupying, in regard to the profession of chemistry, a position corresponding to that which was occupied by the College of Physicians towards the profession of medicine, and various other parallels and comparisons had been drawn with it. The Institution of Civil Engineers had been quoted as an instance of the sort of body which it ought to imitate. He ventured to say that the Institute of Chemistry was successfully imitating this greater and older Institution in every respect but one. It was carrying on its work in a thoroughly efficient and satisfactory manner. It was doing that which he considered to be the main object of its

existence, namely, testing the professional qualifications of the younger chemists by a proper system of examination following upon a course of systematic study, and putting upon them a certain stamp; and it gave them a kind of position in the professional world. He did not know that the College of Physicians or the Institution of Civil Engineers did any more than this; but the difference was that the older bodies had command of very considerable monetary resources. He believed that the Institute of Chemistry only required to be in a stronger financial position to become one of the most influential bodies which existed in the Metropolis, or in this country, and, though he really did not know how it was to be done, he suggested to the President and Council, now that they had set their house in order, and had a roof of their own over their heads, and were carrying on work that was of eminent practical value and eminently serviceable to the community, that they ought to proceed somehow or other to get money. Then, he thought, the Institute would be in a really important position, and capable of exercising that kind of influence upon public opinion which at present it was not in a position to exercise. This was the advice that he now ventured to offer to the Institute; how it was to be carried out he left it to the President and Council to take into early consideration. He would not like to conclude without coupling with this toast the name of the present President of the Institute of Chemistry. The present President lived in happy times. The Institute was no longer divided by those sharp contentions, no longer disturbed by those fierce discussions which took place a few years ago, when he (Professor Tilden) was on the Council. The present President had a united Council to work with, and a definite and fixed organization of the Institute and its work to preside over, and he might say that Dr. Stevenson had shown that he possessed the qualities of the best President that the Institute could have. He certainly was a man representing the sort of professional position that the Institute desired; he was a man of peace, and at the same time a man of action, and he (Professor Tilden) was sure that under Dr. Stevenson's guidance the Institute would go on and prosper more and more year after year.

Dr. Stevenson in returning thanks, in the name of the Institute of Chemistry, for the kindness with which this toast had been proposed and received, said that Professor Tilden had omitted one very important fact, namely, that he (Professor Tilden) was himself one of the former Presidents of the Institute who fought those battles of which he had given such a graphic description. He (Dr. Stevenson) felt that as President of the Institute of Chemistry he had indeed fallen upon very happy times. He was present in somewhat of a double character, for he was present as one of the oldest members, and as a former President, of this Society, as well as in the capacity of President of the Institute of Chemistry; and he felt it a great compliment that as soon as he ceased to be President of the Society of Public Analysts he became the President of the Institute of Chemistry. The times, he hoped, were past when there was any feeling of uncordiality between that Society and the one which he officially represented. He ventured to think that the Institute was conferring a great benefit upon the Society of Public Analysts. It had already instituted examinations which, for completeness in testing professional and chemical knowledge, surpassed those of any other society. Its membership was now without question accepted by the Local

Government Board as a complete qualification in everything required of a public analyst except therapeutics, and with regard to therapeutical knowledge he hoped that the gap would soon be bridged over, and that the Institute would formulate a complete qualification for Public Analysts, as far as the Local Government Board was concerned.

Mr. BERTRAM BLOUNT, in proposing the toast of "Kindred Societies," said that among the societies coming under this head the Chemical Society might properly claim the first place. Analysts, unless they received an education in the science of chemistry as distinct from its profession, would have a remarkably poor chance of success, and if they were unable to produce evidence of a knowledge of the science as such, they would not be proper representatives of a great and growing and most honourable profession. He was therefore sorry to have to refer to the absence of the President of the Chemical Society, Professor Dewar, consequent upon lecture engagements in Cambridge; though they welcomed three most eminent members of the Chemical Society, namely, Professor Armstrong, Professor Dunstan, and Mr. Groves. He coupled the toast with the name of the President of the Society of Chemical Industry, Professor Clowes.

Professor CLOWES, in responding, said that in addition to the society which he had the honour to represent, he had to speak on behalf of several other societies, and he had been greatly assisted by the kindness of Mr. Blount in enumerating them. He considered it remarkable that in spite of the increased number of societies, their membership showed no signs of decreasing. He was not aware that the Chemical Society had suffered in any way from the existence of the Society of Chemical Industry, and he was quite sure that the latter society had not suffered in any way from the existence of other societies, the fact being that its membership was increasing faster than ever. Every one of these societies was really required, and each had been constituted to meet an acknowledged need. He returned hearty thanks for the toast on behalf of all the societies that had been referred to, and expressed the hope that they would all continue to work in a friendly way with the Society of Public Analysts.

Mr. WALTER HILLS (President of the Pharmaceutical Society), in proposing the toast of "The Society of Public Analysts," said that probably most of those present were members of the Society of Public Analysts, and would naturally feel a great interest in its prosperity, and he was sure that that prosperity would continue to increase as long as the Society's object continued to be the benefit of the public. His opinion was that no society could flourish unless it existed primarily for the advantage of the public, and he believed that the Society of Public Analysts was doing good work in the interests of the public. It therefore gave him very great pleasure to propose prosperity to it. Mr. Kearley had referred to the Bill which had been recently introduced in the House of Commons by Mr. Chaplin. He (Mr. Hills) had great sympathy with all that Mr. Kearley had said, and would only say in addition, with regard to the calling which he had the honour to represent, that he was sure it would be agreed that, in the Board of Reference which had been recommended by the Select Committee, there should be someone who was representative of the great pharmaceutical interest, for the examination of drugs was attended by more difficulties, perhaps, than the examination of ordinary

articles of food. The subject of milk had often been discussed rather as typical of those matters which came constantly under the purview of the Public Analyst; but the difficulties arising in connection with milk were intensified in the case of drugs. The subject of milk, moreover, was free from the special difficulties arising from the use of synonyms, which were a great bugbear in connection with drugs. Another difficulty was that many drugs were collected by totally unqualified persons, who did not know the right time to collect these various vegetable products, and who sent to this country products possessing widely different pharmaceutical and therapeutical values. With regard to the Society of Public Analysts itself, it had been in existence for some four-and-twenty years, and had been constantly progressing. It was formed for the protection of the public, it had the interests of the public at heart, and it was trying to furnish for the service of the public a number of persons possessing certain special qualifications. It was, moreover, the proprietor of the ANALYST, which was a most valuable periodical. With the proposition of prosperity to the Society of Public Analysts, he had the pleasure of coupling the name of the Society's President.

The PRESIDENT, in acknowledging the toast on behalf of the Society, referred to the self-sacrificing and indefatigable labour of Dr. Sykes in editing the ANALYST, with results which he thought were satisfactory to every reader of that journal, and the readers of the ANALYST were not merely the members of the Society. The paper went abroad all over the world, and was taking up a very strong position wherever the English language was read, and wherever analytical chemistry formed a subject of interest. He hoped that when the time came for him (the President) to finally resign his official connection with the Society, he would be able to congratulate it upon the fact that the great question of the amendment of the Sale of Food and Drugs Act, which had been exercising their attention for so many years, had been finally settled.

Mr. CASSAL proposed the toast "The Guests."

Professor ARMSTRONG, in replying, said that the Society was doing a work on behalf of the public which was of extreme importance. It was not necessary for him to say more than this in returning the guests' most hearty thanks for the toast.

The health of the Honorary Treasurer, Mr. E. W. Voelcker, and of the Honorary Secretaries, Mr. Edward Bevan and Mr. Charles E. Cassal, having been proposed and acknowledged, the proceedings terminated.

FOODS AND DRUGS ANALYSIS.

The Determination of Fat and Water in Cheese. A. Devarda. (*Zeit. anal. Chem.*, 1897, xxxvi., 751-766.)—The author recommends the following as a simple method of obtaining the fat without material alteration and without free fatty acids or lactic acid. From 50 to 100 grammes of the cheese cut in small pieces (or triturated with a little water in a mortar) are mixed with 50 to 80 c.c. of water, and 100 to 150 c.c. of ether in a Wolfbauer shaking flask (a stoppered flask with a small constriction in the middle). Two or three drops of phenolphthalein solution are added, and the whole well shaken with dilute potash until the aqueous layer becomes perceptibly pink. The ethereal layer is then drawn off, the ether distilled, and the fat dried at 100° C., filtered if necessary, and examined in the usual way. A table giving the constants of the fat thus obtained from fifty-one kinds of cheese (including margarine cheese) is given in the paper.

For the determination of the water about 10 grammes of the finely-divided cheese are dried in vacuo over sulphuric acid at the ordinary temperature for 24 to 36 hours, and then for 2 to 6 hours at 100° C., until the weight becomes constant. In this way the bulk of the water is removed at the ordinary temperature, and whilst the method is as speedy, there is no material loss of organic matter (volatile glycerides and acids) such as occurs with long-continued drying at 100° C. Complete drying in vacuo is too tedious, and often impracticable. The following examples show the accuracy of this process:

Cheese.	Loss of Water per cent.			Water per cent.	Per cent. Water.	
	24 hours in vacuo.	A second 24 hours in vacuo.	3 to 6 hours at 100° C.		Dried entirely at 100° C.	Dried entirely in vacuo.

The Composition of some Commercial Powdered Extracts of Liquorice. C. O. Kinsey. (*Amer. Journ. Pharm.*, 1898, lxx., 23-25.)—The method most in use for the determination of glycyrrhizin, on the amount of which the value of extract of liquorice extract depends, consists in exhausting the extract either with boiling water, cold water made alkaline with ammonia, or with a cold mixture of water and alcohol made alkaline with ammonia, and precipitating the glycyrrhizin in the filtrate with dilute sulphuric acid. But the author, finding the directions given by

other chemists vague, and often experiencing considerable difficulty in filtering the insoluble residue, made experiments, and found that the most satisfactory results could be obtained by using as a solvent a mixture consisting of official alcohol 240 c.c., official ammonia water 40 c.c. (*Amer. Pharmacopœia*), and water to make up a litre.

One gramme of the extract was treated with 25 c.c. of the solvent, stirred at intervals for an hour, and left for twelve hours. The supernatant liquid was decanted on to counterpoised filters, the residue washed with 5 c.c. of the solvent, then transferred to the filters, washed till the washings were colorless, and dried in the air-bath at 100° to 110° C.

The filtrate was acidified with dilute sulphuric acid, and the precipitate of glycyrrhizin collected on counterpoised filters, washed until free from sulphuric acid with water containing a little acetic acid, dried in the air-bath at 105° C., and weighed.

The following table gives the percentage results obtained with samples of different commercial brands:

Brand.	Moisture.	Ash.	Insoluble Matter.	Glycyrrhizin.

C. A. M.

A Reaction for Chloroform, Bromoform, and Chloral. A. Desgrez. (*Ac. d. Sc.*, 1897, 780; through *Jour. Pharm. Chim.*, 1898, vii., 35, 36.)—Chloroform is decomposed by aqueous potash, giving as the principal products carbon monoxide and water in accordance with the equations:—

$CHCl_3 + 2KOH = 2KCl + H_2O + CO + HCl$ and $CHCl_3 + KOH = KCl + 2HCl + CO$.

The carbon monoxide may be recognised by its blue flame, by its absorption in a solution of cuprous chloride in hydrochloric acid, by Berthelot's test (ammoniacal silver nitrate), and by the result of combustion with oxygen in the eudiometer.

The reaction is accelerated by a gentle heat, and by the presence of light. Bromoform is decomposed in a similar manner, though more slowly, but iodoform, being insoluble in water, is not affected, as is also the case with carbon tetrachloride and methylene chloride. Chloral gives the same reaction as chloroform, but more

rapidly on account of the heat generated by its primary decomposition into chloroform and formate accelerating the action of the potash. Alkaline carbonates and bicarbonates do not cause an analogous decomposition, and ammonia is also without action in the cold. C. A. M.

ORGANIC ANALYSIS.

On Douro Olive Oil. A. J. F. Silva. (*Bull. Soc. Chem.*, 1898, xix., 88-89.)—Milliau was the first to point out that certain kinds of olive-oil contained a coloring matter derived from the aqueous part of the pulp of the fruit which gave a rose coloration with Baudouin's reagent. He also showed that by applying the test to the dried fatty acids instead of to the oil itself, the effect of this might be obviated. Domergue established the same fact in the case of olive-oil from Tunis and Algiers, whilst Villavecchia and Fabris found that some varieties of Italian oil behaved in the same way. Similarly the author finds that the best varieties of Douro oil give a violet coloration with sugar and hydrochloric acid, but that their dried fatty acids give a negative result. The samples examined were perfectly normal in appearance and taste, and as regards their physical and chemical constants.

As Toche's reagent gave no coloration with these oils, the author prefers it to Baudouin's for the detection of sesame-oil in olive-oil. Fifteen grammes of the oil are shaken with an equal quantity of a solution of 2 grammes of pyrogallol in 30 grammes of hydrochloric acid, and after being left for some time, the oily layer is decanted, and the hydrochloric acid warmed for five minutes. The appearance of a reddish-purple colour denotes the presence of sesame-oil. C. A. M.

Testing Oil Paints. H. Loesner. (*Chem. Rev. Fettu. Harz-Ind.*, iv. [24], 329-330.)—In order to determine the permeability of a paint, and consequently gauge its value as a protective coating for iron, the author proposes to employ a steam test. A thin, uniform layer of the paint is applied to the surface of a polished strip of sheet-iron (2 by 4 inches), followed by a second coating when the first is dry. The strip, when dry, is then laid, with the painted side downwards, over the opening in a water-bath, and supported by strips of wood (to prevent mechanical injury) so that the surface of the paint is two inches above the constant level of the water. After exposure to the steam of the bath for fifteen hours, the strip is dried at a maximum temperature of 100° C., and after loosening and removing the paint with aniline, its surface is examined for rust.

Resistance to acids may be tested by exposing the painted strips to the fumes of 33 per cent. hydrochloric acid at 20° C., the distance between the surface of the paint and the level of the acid being the same as in the steam test. The incrustation formed on the paint must be removed by washing at intervals, and at the end of twelve hours the paint is removed as before and the metal examined for corrosion.

The steam test is also useful for examining fats, vaseline, lacquers, etc., intended

for use as rust preventors. Any of these substances that will stand the test for four to five hours may be regarded as satisfactory, but for oil paints twelve hours is the minimum exposure permissible. C. S.

Characteristics of some scarce Resins. K. Dieterich. (*Chem. Rev. Fett u. Harz-Ind.*, vol. iv. [24], 327-329.)

Crude Chicle Gum, obtained from *Achras Sapota*, is particularly rare. It contains 70 per cent. of resin, 10 per cent. of gum, 9 per cent. of calcium oxalate, 5 per cent. of sugar and inorganic salts. The pure resin can be extracted by carbon disulphide; it forms a plastic mass, which resembles guttapercha, and can be vulcanized.

Guaiacum in lacrymis, another scarce resin, gives an acid number, 72·8-75·6, by the author's method, whilst that of the ordinary guaiacum is 89·6-92·5.

Socotra Dragon's Blood. The pure red resin from this variety is a mixture of several resins, and differs from Palm Dragon's blood in lacking the draco-alban, characteristic of the latter. Apart from this and their varying solubilities, little difference exists between their other characteristics.

Bisabol Myrrh differs from the ordinary Herabol myrrh of commerce. To prevent errors—arising from the examination of the alcoholic extract instead of the natural drug—the author proposes the following method of determining:

1. *The Acid Number.* One gramme of a very finely powdered average sample of the myrrh is heated along with 30 c.c. of water for a quarter of an hour under a reflux condenser, and then for a similar period with 50 c.c. of strong alcohol. After cooling, the liquid is titrated with $\frac{N}{2}$ alcoholic potash, using phenolphthalein as indicator.

2. *Saponification value.* One gramme of an average sample is infused in 30 c.c. of water, and after standing for half an hour, mixed with 33 c.c. of $\frac{N}{2}$ alcoholic potash, boiled for half an hour under a reflux condenser, then cooled, diluted with alcohol, and titrated back.

3. *Ester number* by difference as usual.

The following values were obtained for the two varieties:

	Acid Number.	Ester Number.	Saponification Value.	Solubility in Alcohol.
Bisabol Myrrh	20·06	125·54	145·6	50 per cent.
Herabol Myrrh	25·48	204·12	229·6	20 per cent.

C. S.

The Preparation of Absolute Alcohol by means of Calcium Carbide. P. Yvon. (*Jour. Pharm. Chim.*, 1898, vii., 100-102.)—Calcium carbide furnishes a ready means of determining whether alcohol is anhydrous or not. On adding a pinch of the powder to several c.c. of absolute alcohol, no bubbles of gas are liberated and the liquid remains transparent, whilst if only a trace of water is present, bubbles of acetylene are liberated, and the liquid becomes milky from the formation of calcium hydrate.

In order to prepare absolute alcohol from 95 or even 90 per cent. alcohol, the latter

is mixed with about one-fourth of its weight of powdered calcium carbide, shaken at intervals during two or three hours, and then left for twelve hours, when all liberation of acetylene should have ceased. It is then cautiously distilled, the first portion, which contains acetylene, being rejected. The alcohol obtained is usually anhydrous, but it is advisable to redistil after the addition of a little copper sulphate to remove acetylene. C. A. M.

Reducing Action of Mineral Acids on Fehling's Solution. M. Z. Jovitschitsch. (*Berichte*, 1897, 2,431.)—The author finds that the addition of small quantities of the mineral acids to Fehling's solution by lessening its alkalinity effects its reduction, even when the liquid is still alkaline to litmus paper, just as effectually as such reducing bodies as glucose, phenylhydrazin, etc. Often the action commences before the liquid is warmed, as in the following case: If to 1 or 2 c.c. of Fehling's solution a few drops of a dilute mineral acid are added in quantity insufficient to discharge the blue colour, and then a few drops in the original Fehling, a turbidity indicating reduction immediately appears, which may be completed by gently heating the liquid. Tartaric acid, employed in a similar manner, also causes reduction. The cause of this is supposed to be the decomposing action of the mineral acid on the tartaric acid of the Fehling's solution; and the reduction which occurs when this solution is kept for some time in well-closed bottles is attributed to spontaneous decomposition of the tartaric acid. W. J. S.

The Chemical Examination of Saliva. E. Gerard. (*Jour. Pharm. Chim.*, 1898, vii., 12-15.)—This paper deals more especially with a pathological case in which an excess of saliva was secreted by an epileptic patient, but also contains remarks on the composition and analysis of normal saliva. The analytical results obtained by the author were: Density at 15° C., 1·003; total solids, 7·85 per cent.; ash, 4·80 per cent.; substances precipitable by alcohol, 2·30; mucin and albumin, traces.

The proportion of salts here is higher than in normal saliva, and bears out Heidenhain's law that the more rapid the secretion, the greater the percentage of mineral matter.

It has been shown by several chemists (*e.g.*, U. Gautrand, *Thèse de Lyon*, 1895) that the amylolytic power of saliva shows a considerable variation under the influence of different diseases. For this determination Jawein's method (*Wien. Med. Press*, xxxiii., 626) was adopted. To 100 c.c. of a 4 per cent. solution of starch 4 c.c. of the saliva were added, and the mixture kept at 39° to 40° for fifteen minutes. It was then diluted to 200 c.c., and the percentage of maltose determined. This varied on different days from 0·603 to 0·639 gramme, whereas normal saliva yields from 0·368 to 0·555 gramme.

The temperature at which the ptyalin became inactive was determined on the ptyalin itself, obtained by precipitation with alcohol and dissolved in water, following the directions of E. Bourquelot (*Ferments Solubles*, 1896, 136). In the author's case the ptyalin was still active at 57° C., became enfeebled at 58° to 59° C.,

and inactive at 60° to 61° C. In this respect it behaved like the ptyalin of normal saliva.

This saliva contained an oxidizing ferment, which has also been found in the normal secretion by P. Carnot (*C. R. Soc. Biol.*, May 29, 1896). C. A. M.

The Influence of Certain Drugs on the Analysis of Urine. B. Bardach. (*Zeit. anal. Chem.*, 1897, xxxvi., 776-784.)—I. *The Influence of Nitrates on the Determination of Nitrogen by Kjeldahl's Method.*—In order to obviate the loss which occurs when the nitrogen in urine containing nitrates is determined either by Kjeldahl's original method, or by the Jodlbauer-Foster modification, or with the addition of phenol to the sulphuric acid, the author has devised the following process, in which the nitrates are first reduced in alkaline solution: Ten c.c. of the urine are placed in a 500 c.c. Kjeldahl flask, together with about 0·3 gramme of aluminium strips (previously heated), 20 c.c. of water and 5 c.c. of soda-lye (specific gravity 1·34) added, and the flask rapidly connected with an absorption flask containing a known quantity of standard sulphuric acid. The flask is left for about forty-five minutes, being occasionally shaken, and is then heated on a wire gauze over a small flame for about five minutes, until the development of gas has practically ceased. The flask is then cooled by drawing air through it, 30 c.c. of concentrated sulphuric acid added (and subsequently some potassium permanganate), the liquid heated until colorless, and the ammonia distilled over in the usual way.

The following are some of the results thus obtained, calculated on 100 c.c. of the urine:

Nitrogen of the Urine. Grammes.	Added Nitrogen in the form of Nitre. Gramme.	Total Nitrogen Calculated. Grammes.	Total Nitrogen Found. Grammes.
0·884	0·348	1·23	1·25
0·788	0·069	0·857	0·849
1·000	0·173	1·173	1·169

II. *On the Determination of Urea by Liebig's Method.*—Salkowski (*Pflüg. Arch. f. Phys.*, vi., 244) pointed out that potassium iodide had an influence on the determination of urea, since, owing to the formation of mercuric silver iodide the end-point of the reaction occurs too soon, and the amount of urea found is too low. This error, however, is considerably modified by the addition of sodium chloride, and owing to the presence of that salt in normal urine is comparatively trifling.

The author finds that ammonium chloride has a similar disturbing influence, but in the opposite direction, delaying the end-point of the reaction, and causing the amount of urea to appear too high. This error is considerable with little more than 0·3 per cent. of ammonium chloride, and with larger quantities the results are entirely worthless.

III. *On the Determination of Uric Acid.*—Experiments are described which prove that the usual doses of lysidin and piperazine have no appreciable effect on the results of the determination of uric acid by Salkowski's method (*Prak. d. phys. u. path. Chem.*, 239). Similarly in the case of potassium iodide the author obtained correct results, although great care was necessary to avoid loss. C. A. M.

INORGANIC ANALYSIS.

Solubility of Copper Sulphide in Sodium Sulphide. A. Hollard. (*Ann. de Chim. Analyt.*, ii. [13], 242.)—By digesting out of contact with the air pure precipitated copper sulphide for a sufficient time with concentrated sodium sulphide (specific gravity 1·225), prepared according to the directions given by Classen, and saturated with hydrogen sulphide, it was found, after filtering the liquid with due precautions to prevent oxidation and throwing down the dissolved copper by electrolysis, that the maximum amount of copper in the condition of sulphide that can be dissolved by 100 c.c. of sodium sulphide is 0·0032 gramme. C. S.

The Separation of Thorium from Cerium. E. Hintz and H. Weber. (*Zeit. anal. Chem.*, 1897, xxxvi., 676-685.)—After experimenting with different analytical methods, the authors have arrived at the conclusion that the separation of thorium from cerium by means of sodium thiosulphate is not absolute, a small amount of thorium remaining in the solution and of cerium in the precipitate, but the errors resulting from this are only trifling, and to a large extent compensate one another.

The separation by means of ammonium oxalate is also incomplete in a single precipitation, and, although better results can be obtained by repeated precipitation, yet the amount of cerium formed is still slightly too high in spite of the fact that traces of cerium can be detected in the filtrate. Very small quantities of thorium oxalate, however, can be completely dissolved by one treatment.

Glaser's method (ANALYST, xxi., 274), based on the solubility of thorium oxalate in a solution of ammonium oxalate containing ammonium acetate, has, according to the authors' experiments, the same drawback, and they recommend the thiosulphate method as being the most satisfactory for the analysis of incandescent mantles and thorium nitrate. The most accurate results are obtained by adding ammonia to the filtrate from the thiosulphate precipitation, dissolving the precipitate in acid, expelling the latter by evaporation, adding oxalic acid, and extracting the small amount of thorium oxalate with ammonium oxalate. C. A. M.

On the Determination of Insoluble Phosphorus in Iron Ores. C. T. Mixer and H. W. Dubois. (*Jour. Amer. Chem. Soc.*, 1897, xix., 614-619.)—The following simple process is based on the fact that ignition of the residue insoluble in hydrochloric acid converts the insoluble phosphorus into a soluble form: About 1½ gramme of the ore is treated with 25 c.c. of hydrochloric acid (specific gravity 1·10), and when as much as possible has dissolved, the excess of acid is expelled by evaporation, and the liquid diluted and filtered. The residue and filter paper are ignited in a platinum crucible at a red heat for a couple of minutes, the mass being stirred with a platinum rod. It is then placed in a beaker with a little water and a few drops of hydrochloric or nitric acid, the liquid gently boiled for about five minutes, filtered into the flask containing the first filtrate (or into another flask if this portion is to be determined separately), neutralized with ammonia, and the phosphorus precipitated as ammonium phosphomolybdate and titrated.

The results obtained in this way are in close agreement with those given by the older method of dissolving the ore and fusing the residue with sodium carbonate. The authors' objections to the latter are, that a longer time and larger crucibles are required for the fusions, and that the introduction of a sodium salt is often unfavourable to the obtaining of a pure precipitate of ammonium phosphomolybdate.

C. A. M.

Determination of Citrate-Soluble Phosphoric Acid in Thomas Phosphate Meal. O. Böttcher. (*Chem. Zeit.*, xxi., 993.)—In a recent paper on the valuation of phosphates according to their citrate-solubility (*Chem. Zeit.*, xxi., 905; ANALYST, xxii., 334), P. Wagner shows that the phosphoric acid in a citrate-extract of Thomas phosphate can be precipitated free from silica direct by magnesia, without the intervention of the molybdenum process, provided that the alkaline citrate and magnesia mixture are added while the extract is fresh. The author claims priority for this observation, as in a paper sent to the *Chem. Zeit.* about a month before Wagner's communication he stated that it was necessary that the citrate solution and magnesia mixture should be added as soon as possible after the extract was ready—at the latest within the same day.

Wagner further states in his paper above referred to that it makes no difference whether the ammonium magnesium phosphate be filtered off immediately after stirring, or after standing for two hours. The author, remarking upon this, observes that he has already, in an earlier paper, called attention to three cases in which silica was deposited in citrate-extracts of Thomas phosphate meal on standing for two hours after precipitation, thus seriously vitiating the results. Though such cases may be rare, it is nevertheless necessary to take into consideration the possibility of their occurring, and therefore the filtration should be carried out promptly. It is also important that the shaking should be commenced immediately after the addition of the citrate solution and magnesia mixture. H. H. B. S.

Wagner's Method for the Determination of Citrate-Soluble Phosphoric Acid in Thomas Phosphate Meal. B. Sjollema. (*Chem. Zeit.*, xxi., 999.)—The author recommends the following procedure: To 50 c.c. of citrate-extract, prepared according to Wagner's directions, are added 50 c.c. of an alkaline citrate solution (containing in 5 litres, 500 grammes citric acid, and 4 litres ammonia of 0·96 specific gravity) and 15 c.c. of magnesia mixture (containing in 2 litres, 110 grammes magnesium chloride, 140 grammes ammonium chloride, and 700 c.c. ammonia of 0·96 specific gravity). The solution is shaken for ten minutes, allowed to stand for two hours, or until the following day, and filtered off. In very few cases does any silica separate. When, however, this difficulty is encountered (which is evidenced by the appearance of the precipitate and the slowness of the filtration), the determination is recommenced, and the solution shaken for half an hour and then at once filtered off. In many cases the author tests the pyrophosphate for silica after weighing by dissolving in hydrochloric acid. H. H. B. S.

Gravimetric Method of Estimating Phosphoric Acid as Ammonium Phosphomolybdate. T. S. Gladding. (*The American Fertilizer*, 1898, i.)—To the solution (25 c.c. to 50 c.c., corresponding to 0·25 gramme of substance) is added 25 c.c. of ammonia of 0·9 sp. gr., and sufficient nitric acid of 1·42 sp. gr. to neutralize the ammonia and produce an acid reaction. The beaker containing the solution is then placed in a water-bath, heated to a temperature of 50° C., and about 10 c.c. excess of ordinary 5 per cent. molybdate solution added from a burette at the rate of about three drops per second, with constant stirring. The beaker is allowed to remain for a further ten minutes in the bath, and the solution is then filtered off through a weighed filter. The filtrate (without the washings) should remain clear, or only show a slight opalescence, on the addition of 5 c.c. of molybdate solution, and further heating for ten minutes in the bath. The precipitate is washed three times by decantation, and three times on the filter with dilute nitric acid (100 : 1), followed by one wash with water. The filter is then drained on blotting-paper and dried at 105° C. The presence of so large a quantity of ammonium nitrate ensures complete precipitation, and by the low temperature employed the separation of molybdic oxide or iron salt is avoided. For the final drying at 105° C. a bath containing dilute glycerol (1·160 sp. gr.) is used.

Experiments undertaken to determine the exact composition of the yellow precipitate dried at 105° C. gave results corresponding to the formula

$$24MoO_3,P_2O_5,3(NH_4)_2O + 24MoO_3,P_2O_5,2(NH_4)_2O,\ H_2O + 5Aq.$$

H. H. B. S.

On the Determination of Phosphoric Acid as Magnesium Pyrophosphate. H. Lasne. (*Bull. Soc. Chim.*, 1897, xvii., 823-832.)—In this paper the author describes at length his experiments on the accuracy of the determination of phosphoric acid by precipitation as a magnesium salt. He finds that rapid precipitation gives an excess of magnesium in the precipitate owing to the partial formation of trimagnesium phosphate, which only becomes transformed into ammonium magnesium phosphate after contact for sixteen hours with ammonium citrate in sufficient concentration (10 grammes in 150 c.c. of liquid). It is necessary, therefore, in order to obtain absolutely accurate results, to allow the precipitate to stand overnight. But this source of error is too trifling to lead to the rejection of the well-known rapid method (which the author describes as "citro-mechanical") for industrial purposes. The transformation of tri-magnesium phosphate into ammonium magnesium phosphate is very slow in the presence of ammonium chloride alone, and the amount of citrate mentioned above ought always to be added.

The precipitation of magnesium by means of an excess of ammonium phosphate gives at the same time as the ammonium magnesium phosphate a phosphate containing less magnesium, and the greater the excess of phosphate, the less the magnesium obtained in the precipitate. This is shown in the following tables, in which the results were obtained by dissolving a known quantity of strongly calcined magnesia in hydrochloric acid, and precipitating it as phosphate in the presence of ammonium citrate:

	A. Gramme.	B. Gramme.		C. Gramme.
Magnesia taken	0·0948	0·1034	Magnesia taken	0·1034
Corresponding to pyrophosphate	0·2630	0·2868	Corresponding to phosphoric acid	0·1834
Weight of calcined precipitate obtained with			Phosphoric acid in the precipitate obtained with	
5 c.c. amm. phosph. (10%)	0·2687	0·2929	5 c.c. of amm. phosph.	0·1940
10 c.c. ,, ,,	0·2709	0·2981	10 c.c. ,, ,,	0·1971
20 c.c. ,, ,,	0·2779	0·3107	20 c.c. ,, ,,	0·2064

From this the author concludes that the results obtained by this classic method of estimating magnesium are always erroneous. C. A. M.

Separation of Crystallized Silica (Quartz) from the Amorphous Variety. G. Lunge and C. Millberg. (*Monit. Scient.*, 1897, [4], xi., 867; through *Chem. Zeit. Rep.*, 1897, 324. Also *Zeits. angew. Chem.*, 1897, 393 and 425.)—In spite of Michaelis's statement to the contrary, caustic alkalies cannot safely be employed to separate amorphous silica from quartz, as they dissolve notable quantities of the latter. Even warm sodium carbonate acts quickly and appreciably on quartz when it has been reduced to a very fine state of subdivision. But in a powdered material, which does not contain any real dust, the solvent powers of a 5 per cent. solution of sodium carbonate are almost entirely limited to the amorphous silica; and the maximum error likely to occur during such a separation will be a deficit of 0·1 to 0·2 per cent. of the total silica on the side of the quartz.

If silicate minerals are powdered as finely as possible, treated with hydrochloric acid, dried at 110° C., and then digested for fifteen minutes with 5 per cent. sodium carbonate on the water-bath, all the silica set free by the acid will be separated from the quartz and the unattacked silicates, but the amount of the former will probably be 0·2 per cent. too high.

Trass and puzzoliana do not contain any free amorphous silica. They are composed partly of quartz and inactive silicates; while their active ingredients consist of zeolites and, in particular, of a silicate of sodium and aluminium, resembling analcite, which is completely soluble on the water-bath in 30 per cent. caustic potash. F. H. L.

The Use of Sodium Oxalate in Acidimetry. S. P. L. Sorensen. (*Zeit. anal. Chem.*, 1897, xxxvi., 639-643.)—Normal sodium oxalate is readily obtained in a pure state by crystallizing the commercial salt from a feebly alkaline solution, washing the crystals with cold water and recrystallizing them. It contains no water of crystallization, is not hygroscopic, and can be weighed out very exactly after being dried at 125° C. or even 150° C. The weighed quantity is then converted into sodium carbonate by moderate ignition in a covered platinum crucible.

Sodium oxalate can also be used for standardizing permanganate solutions, and has the advantage over oxalic acid of not effloresceing. C. A. M.

THE ANALYST.

APRIL, 1898.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, March 16, in the Chemical Society's Rooms, Burlington House, the President (Dr. Bernard Dyer) occupying the chair.

The minutes of the previous meeting were read and confirmed.

Papers were read on "The Composition of Milk and Milk Products," by H. Droop Richmond; "The Calculation of Added Water in Adulterated Milk," by H. Droop Richmond; "Japanese Wood Oil," by J. H. B. Jenkins; "A Typical North-East Lancashire River," by F. R. O'Shaughnessy; and "The Analysis of Marmalade," by L. K. Boseley; and a new form of condenser was exhibited by Mr. C. H. Cribb, B.Sc.

The following gentlemen were elected members of the Society: Mr. H. H. Dains, F.I.C., Mr. A. D. Hall, M.A., Dr. Otto Rosenheim, and Dr. Philip Schidrowitz; and Messrs. A. P. Davson and C. A. Hackman were elected associates.

NOTE ON THE TESTS FOR DISTINGUISHING BOILED FROM UNBOILED MILK.

BY HENRY LEFFMANN.

(*Read at the Meeting, February* 2, 1898.)

IN the ANALYST for August, 1897, p. 211, is a brief note taken from the *Jour. Pharm. et Chim.*, giving several tests for distinguishing between raw and boiled milk. I have repeated these tests under varying conditions, and also tried other analogous reagents. As noted in the original article, the most striking reaction is with 1 : 4 diamidobenzene. When a freshly prepared dilute solution of this substance is added to raw milk, and then a few drops of hydrogen dioxide solution, a deep blue colour at once appears. I have found that the colour is produced to a marked degree when the milk has been heated to 170° F. (76·5° C.), but after heating to 180° F. (82° C.) the property is lost. It seems possible, therefore, to distinguish between pasteurized and sterilized milk. Whole milk, ordinary skimmed and separator-skimmed milk, exhibit substantially the same colour. In addition to the reagents noted in the original report, I have found that the photographic developer, amidol, can be used,

but eikonogen and various amido-, hydroxy-, and carboxy-derivatives of benzene and naphthalene were found to be inactive.

Sour raw milk still shows the reaction, and even when more advanced decomposition has set in, but in the latter case it is less striking.

Some experiments were made with a view to determining what ingredient in the milk causes the reaction. The temperature—about 175° F.—which destroys the effect is about that at which enzymes lose their activity. Various commercial enzymes, malt-diastase, taka-diastase, peptenzyme, pancreatic extract, papaw ferment, pine-apple ferment, and rennet ferment were used without effect. Solutions of blood- and egg-albumin also gave negative results. A sample of raw milk was treated with excess of magnesium sulphate, and the precipitate filtered off. The filtrate gave a deep blue colour with the 1 : 4 diamidobenzene, and a red tint with amidol, but no effect with the other reagents.

A freshly-opened sample of Eagle condensed milk gave no colour. A piece of cheese rubbed up with water also failed to give the reaction.

A solution of the diamidobenzene, after standing an hour or more, gives a slight blue colour with milk, boiled as well as raw, without the addition of hydrogen dioxide, consequently the solution for the test must be freshly made.

COPPER "PURE FOR ANALYSIS."

By James W. Westmoreland, F.I.C., *Associate of the Royal School of Mines, London.*

(*Read at the Meeting, February* 2, 1898.)

Some time ago circumstances which need not be detailed led me to examine a sample of copper-foil, "pure for analysis," which had been obtained from a firm of wholesale chemists. I found it to contain copper, 99·30 per cent. The metal also contained ·02 per cent. of lead, and some arsenic, but was not further examined.

Later I called on the sellers, and found that their representative was by no means ready to admit the impurity of the metal; he stated that it had been supplied to many analysts, but none except myself had complained of the quality. Assuming this copper to be pure, and using it for standardizing volumetric solutions, it is evident that concordant yet very erroneous results might be obtained. For example, in testing material containing 5 per cent. of copper, the results would be 0·035 per cent. too high, with 70 per cent. material 0·49 per cent. too high, while metal containing over 99·3 per cent. would apparently contain over 100 per cent. copper.

I next obtained some "pure copper-foil" from another dealer after requesting the assistant to be careful and give me the pure material. He pointed out the beautifully-planished surface of the metal as a guarantee of its purity, stating that such care would not be taken with ordinary copper-foil. The metal was well planished, but, as in many other cases, the outward appearance was no guarantee of inward purity. It contained copper 99·10 per cent.

It is just possible that the vendor heard indirectly the result of this test, for another sample purchased later was practically pure.

Another firm stated that their pure copper-foil was not electrolytic copper, but was probably nearly as pure, and this turned out to be the case. From another firm samples were obtained marked "Copper-foil Opt," which contained copper 99·81 per cent., and a sample of "electrolytic copper," prepared from purified sulphate of copper, which I have taken as one of my standard samples.

From another London dealer I obtained some copper marked "Free from Arsenic;" this is a specific statement of quality, but on examination I found the metal to contain:

Copper	... ...	99·23 per cent.
Arsenic	... ...	0·67 ,,

The following samples were obtained from a city in the North of England, marked "Copper, pure for Analyses":

(*a*)	Copper	... ...	99·29 per cent.
(*b*)	,,	... ...	99·64 ,,
(*c*)	,,	... ...	99·87 ,,

Other provincial samples gave

(*d*)	Copper	... ...	99·03 per cent.
(*e*)	,,	... ...	99·85 ,,
(*f*)	,,	... ...	99·52 ,,
(*g*)	,,	... ...	99·65 ,,
(*h*)	,,	... ...	pure.

Another sample, described "as pure as it is made," contained copper 99·38 per cent. Another sample, marked "Free from Arsenic," contained copper 99·60 per cent., but was not further examined. I also obtained samples of metal which is sold as "high conductivity copper," and obtained the following results:

(*a*)	Copper	... ...	99·86 per cent.
(*b*)	,,	... ...	99·83 ,,
(*c*)	,,	... ...	99·84 ,,

I have used the electrolytic and iodide methods for determining the percentage of copper in the various samples. It is evident that although samples which give 100 per cent. by the electrolytic test may possibly not be pure, samples which give lower results, say 99·5 per cent., cannot possibly be pure. The samples stated to be "pure" gave practically 100 per cent. by electrolytic test, and gave results agreeing within the error of experiment when used for standardizing thiosulphate solutions for the iodide test, in conjunction with copper obtained by the electrolysis of a solution of the pure sulphate, and of another sample of extremely pure copper, of which I obtained some quantity. Some of the impure samples were also used in this way (taking the percentage found by the electrolytic test)—and gave results agreeing within the limits of experimental error.

Addendum.

Since my paper was read I have obtained two more samples of "electrolytic copper foil," pure for analysis, from a London firm, which contained 99·00 and 99·09 per cent. of copper respectively.

I have also obtained a sample of "pure copper foil" from a provincial dealer, which gave the following extraordinary results on analysis:

Copper	94·42
Lead	0·39
Zinc	4·91
Iron	0·26
Arsenic	traces
	99·98

I submitted a sample of this metal to a firm of London metal workers, who informed me that it was "pure bright rolled copper." The vendor, in answer to inquiries, stated that the metal was obtained some time ago from a London dealer, and that it was marked "Electrolytic copper foil—pure for analysis—free from arsenic."

DISCUSSION.

Mr. BLOUNT said that copper was a substance pre-eminently easy to obtain in a state of purity almost absolute. Nevertheless, the figures obtained by Mr. Westmoreland showed a condition very far removed from purity. At the same time, although this indictment lay against copper sold as "pure for analysis," he could not help thinking that Mr. Westmoreland must have been a little unfortunate in his samples. Copper containing 99·1 or 99·3 per cent. of actual Cu, and sold as pure, was surely a somewhat unusual material, when it was considered that ordinary locomotive firebox copper contained 99½ per cent.—that was to say, it was not only specified to contain, but actually did contain, that quantity, and very often considerably more. He thought it would be interesting to know what was the balance of the impurities in each case. For instance, in the first sample referred to in the paper, containing 99·3 per cent., Mr. Westmoreland had found some arsenic, but had not said how much, or of what the balance consisted. Beside the arsenic, there was presumably something else. The percentage of arsenic found in the sample sold as "free from arsenic," viz., 0·67, was enormous in a refined tough copper, but even in this case a balance of 0·1 per cent. remained unaccounted for. It seemed curious that so many of these arsenical coppers consisted mainly of copper and arsenic, being tolerably free from other impurities. Ordinary tough-pitch copper, containing 99·5 per cent. of actual Cu, and perhaps 0·2 per cent. of lead, would contain possibly 0·15 per cent. of arsenic. At the other end of the scale there might be 0·4 of arsenic, with 99·5 per cent. of Cu, all the other impurities being included in the remaining 0·1. It was just conceivable that some of the samples examined by Mr. Westmoreland were refined but not toughened coppers, and in such case they might very well have been free from most impurities save oxygen. It was impossible, however, to roll into foil copper containing much oxygen, so it seemed fair to assume that foil was not "refined" as distinct from "tough-pitch." The largest quantity of oxygen that could be contained by copper-foil would be about 0·15 or 0·2 per cent., so that the balance left from this and the actual Cu found by Mr. Westmoreland would probably be lead, arsenic, nickel (a common impurity in commercial copper), and the other odds and ends of things generally found. Touching the question of analysis, it was clearly

evident that to obtain reliable results one must either be prepared to isolate the whole of the copper (and he knew of no process of doing this with any degree of accuracy except electrolysis), or one must have a standard for comparison which was unexceptionable. He gathered that Mr. Westmoreland had followed both modes of procedure, and in that case his figures would be gratefully received. He might mention, however, that in the electrolytic method it was necessary, in order to avoid serious errors, to isolate the copper as nearly as possible from a large quantity, *e.g.*, 10 grammes of the sample, and then to determine the residual copper in the solution.

Mr. WESTMORELAND said in reply that, with the exception of one sample of electrolytic copper prepared from the pure sulphate and the three samples of "high conductivity" copper wire, all the samples were copper-foil. The samples were obtained from practically every dealer in the United Kingdom. His (Mr. Westmoreland's) primary object was to obtain pure copper for standardizing volumetric solutions; consequently he had not troubled in most cases to further examine samples when he found they were impure. The absence of other impurities in arsenical coppers containing, as Mr. Blount suggested, 99·5 per cent. of copper and 0·4 per cent. of arsenic, may be explained on the assumption that they are produced from very arsenical blister copper, and that, consequently, the other impurities present are eliminated before the arsenic is reduced to an allowable percentage. He (Mr. Westmoreland) had many years ago pointed out the necessity of determining the residual copper in the solutions from electrolytic assays.

THE COMPOSITION OF MILK AND MILK PRODUCTS.

By H. DROOP RICHMOND.

(*Read at the Meeting, March* 16, 1898.)

Of the 35,007 samples analysed during 1897 in the Aylesbury Dairy Company's laboratory, 28,762 were samples of milk.

The average composition of 12,907 of these, taken on arrival of the milk from the farms at the depots, is given in Table I.

TABLE I.—AVERAGE COMPOSITION OF MILK DURING 1897.

	Morning Milk.				Evening Milk.				Average.

Average ...	1·0324	12·54	3·60	8·94	1·0320	12·98	4·03	8·95	1·0322	12·76	3·82	8·94

It is seen that the composition differs but very slightly from that found in 1896. As usual, the lowest fat was found in June, and the highest during the latter months of the year, and a marked depression of solids-not-fat was noticed in July and August.

The methods used in 1896 have been employed without any modification; in the few cases where the solids-not-fat fell below 8·5 per cent., milk-sugar, proteids, and ash have been determined. The following samples are the only ones showing any abnormality, and were passed as genuine, though not authenticated:

	I.	II.	III.
Specific gravity ...	1·0294	1·0288	1·0355
Total solids ...	12·63	12·34	13·63
Fat	4·35	4·20	3·80
Sugar	4·14	4·13	4·67
Proteids	3·38	3·29	4·35
Ash	0·76	0·71	0·77
Solids-not-fat ...	8·28	8·14	9·83

I have looked through the results of analyses for many years past, and have compiled the following table of the probable number of samples which will be found per 100, having solids-not-fat between the limits named. These figures only refer to the mixed milk of herds:

Percentage of Solids-not-Fat.	Probable Number per 100.
8·4 to 8·5	1·892
8·3 ,, 8·4	0·242
8·2 ,, 8·3	0·027
8·1 ,, 8·2	0·022
8·0 ,, 8·1	0·008
Below 8·0	0·002

It is seen that the proportion of samples appreciably below 8·5 per cent. is excessively small; the bulk of these occur during the months of July and August. I am not in possession of sufficient data to say definitely that the few genuine samples with solids-not-fat below 8·5 per cent. can be distinguished from adulterated milks; but the whole of the samples low in solids-not-fat that I have examined, with whose genuineness I am satisfied (forty-six in all), have had an ash above 0·70 per cent., and nitrogen above 0·50 per cent. On the other hand, all samples to which I have added water have been below those limits, as well as below 8·5 per cent. of solids-not-fat.

I would urge on public analysts the importance of determining the ash and proteids (or nitrogen) on every sample which, from their preliminary results, they consider suspicious.

The preparation of ether for milk analysis has received some attention; the occurrence in commercial ether of an acrid substance, which appears to be obstinately retained by fat, has probably been noticed by all. My first attempts at removing this were by distillation from oil, with a fair amount of success; I have, however, found that by distillation of the ether on a water-bath not exceeding 40° in temperature, from a flask fitted with Glynsky's bulbs, a product is obtained which is eminently satisfactory; the last fraction (B.P. 34·6° to 34·8°) can be used for thermo-regulators

for incubators, as at 37° to 38° it has a vapour tension of about 2½ inches of mercury above atmospheric pressure.

In the analysis of cream and clotted cream amyl alcohol has been substituted for ether to dissolve the fat; in this menstruum fat is easily soluble while hot, though it largely deposits on cooling; the other constituents of milk are almost insoluble. A series of comparative experiments showed that no appreciable difference was found between ether and amyl alcohol. Amyl alcohol is readily volatile at 100° in a current of air.

The method used is as follows: 4 grammes of cream are weighed into a large platinum dish and evaporated in the water-oven; after about one hour the solids-not-fat become adherent to the basin, and by inclining it the fat runs away to the lower portion, and the solids-not-fat are left comparatively free from fat. Under these circumstances drying is complete in about five to six hours. To extract the fat 25 c.c. of amyl alcohol are poured on, and the basin placed for a short time in the water-oven; the amyl alcohol is then carefully decanted; the solution of fat can be separated without loss of solids-not-fat if attention be paid to the slow decantation. This process is repeated about eight or nine times, the basin being usually allowed to stand overnight between the fourth and fifth treatments. The following experiment will show the results obtained with ether and amyl alcohol:

	Weight Taken.	Weight after Drying at 100°.	Weight after Four Washings and Three Hours' Drying.
Ether ...	3·9985 ...	2·898 ...	0·246
Amyl alcohol	3·998 ...	2·894 ...	0·2405

	Weight after Four more Washings and Three Hours' Drying.	Weight after Four more Washings and Three Hours' Drying.
Ether ...	... 0·240 ...	0·2385
Amyl alcohol	... 0·239 . .	0·238

The solids-not-fat are then dried for about three hours at 100° C. and weighed, the fat being found by difference. Determination of the fat by the Werner-Schmid or Leffmann-Beam methods gives results agreeing within the limits of experimental error:

Fat by Difference.	Werner-Schmid.	Leffmann-Beam.
50·60 ...	50·58 ...	50·14
57·16 ...	57·20 ...	57·35 56·95
51·78 ...	— ...	51·89 51·67
56·73 ...	— ...	56·94

The solids-not-fat left in the basin on incineration at dull redness give the percentage of ash.

Clotted cream analysed by the method given above yielded the following results:

	Maximum.	Minimum.	Average.
Total solids	75·50 ...	55·16 ...	66·64
Fat	67·69 ...	44·29 ...	58·22
Ash	1·11 ...	0·44 ...	0·70
Solids-not-fat	11·51 ...	5·68 ...	8·42

The following percentages of water in butter have been found:

	Maximum.	Minimum.	Average.
English fresh butter ...	14·64 ...	11·59 ...	13·05
,, salt ,, ...	15·44 ...	11·50 ...	13·23
French fresh ,, (X)	17·82 ...	14·30 ...	15·73
,, ,, ,, (Y)	16·31 ...	13·08 ...	14·33
,, salt ,, ...	14·84 ...	9·09 ...	12·73
Danish ,, ,, ...	17·10 ...	8·90 ...	12·58

The English butters were examined within twenty-four hours of churning; it is seen that there is no appreciable difference between fresh and salt butter.

The most notable point is the high percentage of water in French fresh butters; these have been divided into two classes according to the district of origin. Of the X samples no less than 40 per cent. contained above 16 per cent. of water, which has been proposed as a limit, the maximum reaching 17·82, while the average is only just below 16 per cent. Only one sample of series Y contained above 16 per cent. of water. Two samples of Danish salt butter contained above 16 per cent. of water; on microscopic examination the appearance described by Storch (ANALYST, vol. xxii., p. 197) as "thick"—*i.e.*, the presence of enormous numbers of small water-globules—was noticed. They did not appear at all watery on casual examination, but seemed to be slightly "overworked"; salt butters containing a lower percentage of water almost invariably look "wet" if a short period after churning has elapsed. The French fresh butters did not appear "thick," but had a tendency to break off short, or, in other words, had a low tensile strength.

The manufacturers of the X butters have evidently worked out a method for retaining a somewhat large percentage of water, without in any way deteriorating the flavour or keeping qualities; seeing that the same thing occurred in 1895, and to a lesser extent in 1896, I believe I am justified in regarding the extra average percentage of water (2 per cent.) as an addition. An interesting and difficult question is raised: Is this addition (which may be safely assumed to be commercially successful) to be regarded as an adulteration, seeing that the essential qualities of the butter (flavour, texture, etc.) are not only retained, but manifest themselves in a high degree? I may add that there was no suspicion of adulteration by margarine; the butyro-refractometer results usually fell between 45° and 46° at 35° C., and never appreciably exceeded 46°.

DISCUSSION.

Mr. BEVAN inquired what was regarded as the particular advantage of amyl alcohol over ether in the determination of fat. Unless absolutely pure, it would contain substances boiling at a high temperature, which he doubted very much would be volatile at 100° C., even in a current of air.

Mr. L. K. BOSELEY said that it was never suggested that amyl alcohol should be used in a Soxhlet, but merely for extracting the fat from quantities of, say, 100 grammes of butter, the advantage being that it could be boiled in a water-bath without loss. Amyl alcohol would extract fat much better at a high temperature than ether would at a low one; and any residual non-volatile substances could be afterwards washed out with ether.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

A Delicate Test for the Detection of a Yellow Azo Dye used for the Artificial Coloring of Fats, etc. J. F. Geisler. (*Journ. Amer. Chem. Soc.*, 1898, xx., 110-113.)—By the food laws of several of the American States, the addition of an artificial coloring matter to oleomargarine is forbidden. The author states that azo dyes have now largely replaced annatto as the coloring substance, and calls attention to the fact that fuller's earth gives a pink or red colour, with at least one, if not more, of these dyes. The dye can be precipitated from the clarified fat by the earth as a violet-red precipitate, which, when washed with naphtha to remove the fat, and dried, leaves a violet-red powder. This is immediately decolorized on contact with alcohol, the colour reappearing on evaporation of the latter. The coloring matter can be extracted with boiling alcohol, and as thus obtained is insoluble in cold and sparingly soluble in hot water. It dissolves in concentrated sulphuric acid with a yellow colour, which changes to red on the addition of water. Other strong mineral acids also produce a violet or pink colour. In the latter particular it behaves like methyl orange, which, however, when pure does not give the fuller's earth reaction.

The reaction, with the help of the microscope, is exceedingly sensitive ; and whilst 14 grains of the coloring matter per ton of fat give a barely perceptible faint yellow tint, a strong pink tint is obtained on spreading ½ gramme of the sample on a porcelain slab, and adding fuller's earth. When the fat is dissolved in naphtha, and the earth added to the solution, the pink appears as a zone at the edge of the deposited reagent.

It is stated that commercially the yellow azo dye is used in combination with an orange dye, and that the latter does not give this reaction. C. A. M.

The Determination of Antipyrine and of Iodine. J. Bougault. (*Journ. Pharm. Chim.*, 1898, vii., 161-163.)—One gramme of antipyrine combines quantitatively with 1·351 gramme of iodine, and on this fact the author bases the following method of estimating these bodies by means of one another. To 20 c.c. of a solution of 1 gramme of antipyrine in 100 c.c. of 95 per cent. alcohol are added 20 c.c. of an alcoholic solution of mercuric chloride (2·5 grammes in 100 c.c.), and the solution of iodine (1·351 gramme in 100 c.c. alcohol) run in until the liquid becomes faintly yellow. The determination of iodine by means of a solution of antipyrine is made in a similar manner. The reaction is instantaneous, and antipyrine has the advantages over thiosulphate of readily being obtained in a pure and dry state, and of remaining unaltered in solution for an indefinite length of time (*cf.* ANALYST, xxii., 219).

C. A. M.

Opticity of Crystalline Digitalin. A. Petit. (*Bul. gén. de Thérap.*, 1897, ii., 748; through *Chem. Zeit. Rep.*, 1898, 36.)—A 2 per cent. solution of absolutely pure crystallized digitalin in 95 per cent. alcohol has an opticity of +11·6° at 18° C.; a solution of the same strength in chloroform rotates the beam +17·2°. Inasmuch as well-crystallized (German) "digitoxin" has the same melting-point and chemical properties, and also exhibits the same rotatory power both in alcoholic and chloroformic solution, the two bodies are manifestly identical. F. H. L.

The Analysis of Liquorice Mass. A. Mellor. (*Amer. Jour. Pharm.*, 1898, lxx., 36, 137.)—The following process has been adopted by the manufacturers and large consumers in the United States:

Moisture.—Two grammes of the mass are dried in the water-oven until hard. The dry residue is then divided into small pieces and the drying repeated until the weight is constant.

Mineral Matter.—The dried mass is incinerated until the ash is white.

Insoluble Substance.—Five grammes are dissolved in 100 c.c. of water, and after twelve hours the sediment is collected on a weighed filter, cold water being used in rinsing out the beaker. A further deposit occurs in the filtrate after another twelve hours, owing to traces of starch passing through the filter. This is collected on a second weighed filter.

Gummy Matter.—Five grammes are dissolved in 50 c.c of boiling water and 100 c.c. of 95 per cent. alcohol added. The liquid is well stirred, and after standing all night the precipitate is collected on a weighed and dried filter and washed with alcohol (95 per cent.) 2 parts, and water 1 part, until the filtrate is colorless. The residue, dried in the water-oven, gives the combined weight of insoluble substances and gummy matter.

Glycyrrhizin.—The alcoholic filtrate from the above is concentrated to a volume of 30 c.c. and transferred to a weighed beaker with the help of about 20 c.c. of water. The glycyrrhizin is precipitated by adding dilute sulphuric acid (12 drops of strong acid to 5 c.c. of water) with constant stirring. After standing all night, the liquid is poured off through a filter and the glycyrrhizin washed three times with ice-cold water, which is decanted each time. After adding 1 drop of concentrated ammonia-water to neutralize any acid, the beaker is dried in the water-oven to constant weight.

Saccharine Matter.—The liquid decanted from the precipitated glycyrrhizin is neutralized with barium hydrate, the barium sulphate separated by filtration, and the amount of saccharine matter in the filtrate determined with Fehling's solution.

Extractive Substance.—This is taken as the difference between 100 and the other constituents determined as above. C. A. M.

ORGANIC ANALYSIS.

A Volumetric and Gas-volumetric Method for the Determination of Hydroxylamine and Hydrazine. K. A. Hofmann and F. Küspert. (*Berichte*, 1898, xxxi., 64-67.)—This is based on the oxidation of hydroxylamine or hydrazine, with a dilute solution of a vanadium salt in sulphuric acid, the nitrogen evolved being collected and measured, and the partially-reduced solution titrated back with permanganate.

I. $2NH_3O + O = N_2 + 3H_2O$. II. $N_2H_4 + 2O = N_2 + 2H_2O$.

Should other reducing substances be present, a deduction is made based upon the amount of nitrogen calculated to hydroxylamine or hydrazine.

The vanadium solution is prepared by dissolving 5 grammes of ammonium meta-vanadate in 50 c.c. of sulphuric acid kept cool, and diluting to 1 litre. The substance to be analysed is dissolved in dilute sulphuric acid, and the vanadium solution added slowly until a green coloration results. The nitrogen evolved at the ordinary temperature is collected, which requires about twenty minutes. The flask is then warmed at about 60° C. for a few minutes, at the end of which the green colour should still remain, and, finally, the solution is transferred to a porcelain dish and titrated with standard permanganate until there is a permanent rose tint.

The following results were obtained with hydrazine sulphate (15 grammes in 1,000 c.c.). The permanganate solution used contained 1·794 grammes of available oxygen per litre.

Hydrazine Solution. C.c.	Vanadium Solution. C.c.	Permanganate. C.c.	Oxygen consumed.	Nitrogen at 0° C. and 760 mm. C.c.
10	50	20·51	0·03680	
10	50	20·23	0·03630	
10	50	20·20	0·03624	
10	50	19·97	0·03583	19·85 = 22·09 per cent.

The calculated amount of nitrogen = 21·58 per cent., and the results were therefore in accordance with the equation $N_2H_6SO_4 + 2O = N_2 + 2H_2O + H_2SO_4$.

The results obtained with hydroxylamine sulphate, hydroxylamine nitrate, and hydrazine mercury sulphate showed a similar agreement with those required by theory. C. A. M.

The Estimation of Phenylhydrazine. H. Causse. (*Bull. Soc. Chim.*, 1898, xix., 147-149.)—This is based on the fact that arsenic acid oxidizes phenylhydrazine, liberating nitrogen, and leaving phenol, and that a corresponding quantity of the arsenic acid is reduced to arsenious acid.

$$As_2O_5 + C_6H_8N_2 = N_2 + H_2O + C_6H_6O + As_2O_3.$$

The reaction is quantitative in an acetic acid solution, and the arsenious acid produced may be estimated either by titrating the standard arsenic acid solution with uranium before and after the reaction, so as to obtain the amount not reduced, or by titrating the arsenious acid produced with iodine in the presence of sodium bicarbonate ($As_2O_3 + 2I_2 + 2H_2O = 4HI + As_2O_5$).

About 0·20 gramme of phenylhydrazine, or preferably of its hydrochloride, are heated gently under a reflux condenser with 60 c.c. of an arsenic acid solution prepared by dissolving on the water-bath 125 grammes of arsenic acid in a mixture of 450 c.c. of water and 150 grammes of concentrated hydrochloric acid, filtering when cold, and making up to a litre with glacial acetic acid. When the bubbles of gas have ceased, the liquid is boiled for about forty minutes and allowed to cool. After the addition of 200 c.c. of water, a solution of caustic soda (free from sulphides) is added until the liquid is just alkaline. Hydrochloric acid is then added to acid reaction, and, when cold, 60 c.c. of a cold saturated solution of sodium bicarbonate are added and the liquid titrated with decinormal iodine.

If V be the volume of iodine solution required, the quantity of phenylhydrazine is obtained from the formula $V \times 00495 \times 0{\cdot}5454$.

The results given by the author agree well with theory, and it is stated that the method is equally applicable to the analysis of compounds of aldehydes and phenylhydrazine, although if the aldehyde belong to the fatty series it should be eliminated on account of its action on the arsenic acid; if, however, it belong to the aromatic series its presence is without effect, and the estimation can be made on the compound itself. C. A. M.

Examination of Wax with the Refractometer. J. Werder. (*Chem. Zeit.*, 1898, xxii., 38 and 59.)—The author finds that the Zeiss butter refractometer may advantageously be employed in the examination of different kinds of wax, especially when the amount of material at disposal is very limited, and that the indications obtained with it are quite as valuable as in the case of oils and fats. Owing to the high melting-point of the wax, it is necessary to work at a higher temperature than usual, preferably 66° to 72° C., and then to reduce the results to the normal temperature, 40° C. As shown in the annexed table, the figures given by genuine beeswax vary from 42·6° to 45·4°, the great majority of specimens falling between 44° and 45°; and it seems to make little or no difference to the refractive power whether they are tested before or after bleaching. Samples 19 to 24 had previously been examined chemically, and had been rejected on the ground of their abnormal acid and ester numbers, which were as follows:

Number of Sample.		Acid Number.		Ester Number.
19	...	18·48	...	66·64
20	...	127·1	...	13·4
21	...	59·08	...	3·36
22	...	104·7	...	14·3
23	...	41·0	...	57·0
24	...	106·9	...	48·1

No. 24 is a product, called "glanzwachs," obtained by adding some of the mixture of stearic and palmitic acids as used in the manufacture of stearin candles (No. 28) to a genuine wax, this being a form of adulteration commonly employed in Switzerland.

F. H. L.

On the Estimation of Unsaturated Fatty Acids. E. Twitchell. (*Jour. Soc. Chem. Ind.*, 1897, 1002-1004.)—The author bases a method for separating saturated from unsaturated fatty acids on the fact that the latter combine (in all probability quantitatively) with sulphuric acid, forming addition compounds which are insoluble in petroleum spirit. As it was found that the saturated acids could not be extracted from a concentrated sulphuric acid solution by petroleum spirit, and that the addition of water decomposed the sulpho-fatty acids, experiments were made with sulphuric acid previously diluted, and eventually 85 per cent. was fixed upon as the most satisfactory strength.

The method of separation tentatively adopted is as follows: From 0·5 to 1 gramme of the fatty acids are melted in a stoppered Erlenmeyer flask, the flask chilled in ice-water, 3 c.c. of 85 per cent. sulphuric acid added, and the temperature allowed to rise. As soon as the action commences a clear solution is rapidly obtained, and the flask is again cooled. Fifty c.c. of petroleum spirit are then introduced, the

flask well shaken, the petroleum spirit decanted into a separator-funnel, the flask rinsed out twice with 10 c.c. of petroleum spirit, and the total extract washed with water, the solvent evaporated, and the residue, consisting of saturated fatty acids, dried and weighed.

Crude oleic acid, solidifying at 12° C., when examined in this way, gave a crystalline residue melting at 37° C., and the following results were obtained with the fatty acids from three different samples of oil:

Origin of Fatty Acids.	Solidifying Point, ° C.	Amount used. Gramme.	Petroleum Spirit Extract, per cent.	Melting-point of Saturated Acids, °C.
Lard	40·75	0·7815	42·35	53·5
Cotton-seed-oil ...	30·89	0·6150	32·60	...
Ditto	31·90	0·5875	23·91	53·0

From the melting-points of the residues being somewhat low, the author did not consider the saturated acids thus obtained quite pure, although the impurity must have been slight.

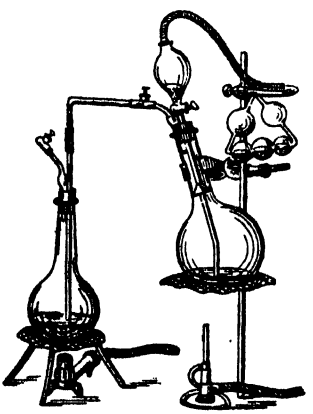
A second extraction of the sulphuric acid solution of the cotton-seed-oil fatty acids, with 50 c.c. of ether, yielded 0·019 gramme of residue which did not solidify at the ordinary temperature, such residue being attributed to the decomposition of a small amount of sulphostearic acid.

The petroleum spirit used must first be tested to see whether any non-volatile substances are produced by treatment with sulphuric acid. If so, it can be purified by being digested for an hour at 100° C., with about half its weight of concentrated sulphuric acid, and then washed and distilled. C. A. M.

Estimation of Phenol in Disinfectants in Presence of Soap. W. Spaltehols. (*Chem. Zeit.*, 1898, xxii., 58.)—In the examination of neutral disinfectants, such as creolin, lysol, and "soluble cresol," where the phenols are not in a state of combination, there is no necessity to add any acid before distillation, as recommended by Fresenius and Makin (ANALYST, xxi., 301), since calcium phenolates are readily decomposed when heated in aqueous solutions. The sample is placed in an iron retort and distilled in a current of steam between 200° and 220° C. until the distillate no longer yields any oily matter. Bodies which contain soaps of oleic acid must not be heated above 210°, lest the latter are decomposed; but should this happen, it will at once be rendered apparent by the presence of a layer of oil floating on the top of the water in the receiver. Alkali-rosin soaps easily resist a temperature of 220°. The distillate consists of phenols alone in the case of lysol; of phenols and tar hydrocarbons in the case of creolin, mixed with the water; and the simplest way of separating them is to extract the whole with benzene, remove the aqueous portion, and estimate the phenols themselves with caustic soda. (Koppeschaar's process is not adapted for the analysis of mixed phenols of unknown composition.) Tried on a number of known products, the author's method has given results usually 0·5 per cent., but occasionally 1·0 per cent., below the theoretical; and it is therefore quite accurate enough for ordinary work.

Lysol and "soluble cresol" contain between 50 and 60 per cent. of phenols; creolin from 0 to 28 per cent., although samples which emulsify well with water seldom have more than 18 per cent. The relative values of the two materials, however, cannot be judged merely by the proportion of phenols found in them, for if a creolin gives an oily precipitate on dilution with water, that portion of the substance is wasted; while, on the other hand, the neutral hydrocarbons present also exhibit distinct germicidal properties. F. H. L.

A Reaction distinguishing between Creosotes and Guaiacols. H. Fonzes-Diacon. (*Bull. Soc. Chim.*, 1898, xix., 191, 192.)—A small quantity of the sample is dissolved in water, 2 or 3 c.c. of a solution of copper sulphate (about 4 per cent.) added, and 1 or 2 c.c. of a 4 per cent. solution of potassium cyanide. An immediate striated precipitate is produced, which, viewed by transmitted light, is emerald-green in the case of creosote, grayish-red with poor guaiacol, and maroon-purple with rich guaiacol. The emerald-green colour changes rapidly to yellow. In this way it is possible to determine whether a product is a creosote containing 12 to 25 per cent., a guaiacol containing 65 to 70 per cent., or a guaiacol with 85 to 90 per cent. of crystallizable guaiacol, without having recourse to a colour scale of typical solutions as in Adrian's colorimetric method (ANALYST, xxii., 162). C. A. M.



Detection of Halogens in Organic Compounds. P. N. Raikow. (*Chem. Zeit.*, 1898, xxii., 20.)—Some ten years ago Günzburg recommended the use of an alcoholic solution of phloroglucinol and vanillin to detect free hydrochloric acid in the gastric juice; for the reagent gives an intense permanent red colour on warming therewith, although it is unaffected by organic acids. If the same solution is heated with an organic body containing a halogen, only in a few cases is the red colour produced. If the substance is liquid and combustible, it may be mixed with a few drops of the phloroglucinol-vanillin solution in a flat porcelain basin, and the alcohol ignited. As the spirit burns away, the red colour usually develops; but to render the test universally applicable it is better to operate as follows: A piece of porcelain is moistened with the reagent, the solvent allowed to evaporate, and the dried film (which is now colorless) is held over the flame of a spirit-lamp, into which the suspected substance is introduced on the end of a platinum wire. The test is roughly quantitative, for according to the amount of halogen present, more or less of the surface is turned red. If the organic substance is an inflammable gas, it may be set light to, and the porcelain dish held over the flame. F. H. L.

Estimation of Carbon and Oxygen in Organic Bodies by Moist Combustion. J. K. Phelps. (*Zeits. anorg. Chem.*, 1898, xvi., 85.)

Oxidation of Carbon with Potassium Permanganate.—Many organic substances are completely oxidized on warming with sulphuric acid and permanganate, so that the evolved carbon dioxide may be absorbed in barium hydroxide, and determined with iodine and arsenious acid as previously mentioned (ANALYST, xxii., 55). The apparatus consists of a wide-necked 75 c.c. flask fitted with a stoppered funnel and leading-tube for the gas, the latter being expanded into a bulb immediately over the

cork; and a condensing-flask of 250 c.c. capacity provided with an inlet tube reaching to the bottom and an outlet closed by a screw clamp. The two corks are of rubber, and so long as they do not come in contact with the liquids they will not be attacked. The substance is rinsed into the small flask with 10 or 15 c.c. of water; 3 or 5 c.c. more of standardized caustic baryta solution than is necessary to absorb all the gas is introduced into the larger vessel, the pressure reduced by means of a pump to 200 or 225 mm., the organic solution warmed, excess of permanganate run in through the tube funnel, and, finally, 10 c.c. of 1 : 4 sulphuric acid. The mixture is boiled for five minutes, care being taken to maintain some vacuum, while the receiver is well shaken and kept cold in a basin of water; pure air is then allowed to enter through the funnel to restore the atmospheric pressure, and to drive the last traces of carbon dioxide into the baryta. The cork of the large flask is removed, the tubes washed, another rubber cork carrying a funnel and a set of nitrogen bulbs put in its place; the liquid is heated, decinormal iodine added till it becomes permanently red, then cooled again, and the excess of iodine titrated with decinormal arsenious acid. The permanganate solution should be boiled with sulphuric acid until all CO_2 is driven off; the water and acid must also be boiled till free from the gas. Oxalates may be decomposed very smoothly in this way; but in the case of formates and tartrates more than sufficient pure caustic soda (not ammonia) should be added at first to neutralize the acid in the permanganate, and then, after the whole has been raised to the boil, an excess of dilute sulphuric acid run in as before. The process was checked on ammonium oxalate, barium formate, and tartar emetic; the figures show an average error of about 0·2 milligramme in estimating 0·15 to 0·6 gramme of CO_2.

Oxidation of Carbon with Chromic Acid.—Although a concentrated mixture of chromic and sulphuric acids is a much more powerful oxidizing agent than potassium permanganate, there are many organic substances, as Cross, Higgin, and Bevan have pointed out, which yield some carbon monoxide on treatment therewith. The following arrangement ensures complete oxidation without the necessity for passing the gases over red-hot copper oxide. The construction of the apparatus is explained by the annexed cut. The large flask is made of thick glass and holds 1 litre; the cone in the neck is of platinum, and serves to protect the rubber cork from splashes when the vessel is shaken. The separating funnel holds 100 c.c.; the stopcock is well ground in, and moistened with strong metaphosphoric acid. The condensing flask holds 500 c.c. The substance to be analysed is weighed into a thin glass bulb, the aperture thereof sealed, the bulb dropped into the large flask, and an excess of pure potassium bichromate added. A suitable amount of caustic baryta solution is poured into the condenser, the apparatus put together, 10 c.c. of pure sulphuric acid introduced into the generator, and both flasks are boiled till about 2 or 3 c.c. of water have been evaporated from each, and a vacuum is produced. The flames are removed, the two clamps shut, the little bulb is broken by a jerk, and 20 c.c. of strong

sulphuric acid (previously freed from organic matter by heating with a few crystals of bichromate) run in through the funnel. The flask is well shaken, heated to about 105° C. (the maximum temperature permissible if loss of oxygen is to be avoided), water added to dissolve the chromic acid crystals, and the whole is again boiled (without allowing the pressure to exceed that of the atmosphere) for five minutes with constant agitation. By this time any CO will be oxidized; 60 or 70 c.c. of water are introduced, the clamp between the two flasks is opened, and the carbon dioxide is permitted to pass into the condenser, which is kept cold and shaken as before. The contents of the generator are once more heated to the boil, and a steady current of pure air is passed through the apparatus for fifteen minutes. Finally the CO_2 is estimated in the manner already given.

Estimation of Oxygen. — In the above process, if a known amount of pure bichromate is employed, and the excess of chromic acid remaining unreduced after the operation is determined, it is evident that the quantity of oxygen required to burn the carbon may be calculated; and from the total CO_2 recovered, by a simple subtraction, the oxygen in the original body may be deduced. The only special precaution necessary is that the sulphuric acid shall not become too strong, lest it begin to act on the bichromate, causing the evolution of oxygen instead of chlorine in the second distillation. Twenty c.c. of sulphuric acid are used in the C estimation, and the boiling is allowed to proceed quietly. The volume of water added in the final dilution should be adjusted so as to leave 60 or 80 c.c. in the flask when the CO_2 has been driven off. This liquid is brought into a Voit flask connected with a Drexel washing apparatus containing an excess of sodium arsenite of known strength, and a set of nitrogen bulbs filled with dilute caustic soda. It is treated with 35 c.c. of HCl (specific gravity 1·2), boiled in a gentle current of CO_2, which has been washed in a solution of iodine in potassium iodide and then in KI alone, until some 30 or 40 c.c. have distilled off. Sometimes red vapours of chromyl chloride are produced during the boiling; but as this substance is reduced by the arsenious acid, it is a matter of no consequence to the analysis. The latter liquid is acidified with sulphuric acid, made alkaline with potassium carbonate, and titrated with decinormal iodine.

The double method (for C and O) was tested on ammonium oxalate, phthalic acid, pure sugar, paper, tartar emetic, and barium formate. The results are exemplified in a table: they are, especially for the carbon, eminently satisfactory; the error in the oxygen determinations varies from 0·0 to 2·1 milligrammes in 0·1 to 0·5 gramme. Organic substances which are volatile and yet difficult to oxidize cannot be subjected to this moist combustion: ether is easily oxidized to acetic acid, but it cannot be completely burnt up; for although liquid acetic acid is very rapidly attacked by nascent chromic acid, yet in the gaseous state (as it exists owing to the conditions of the reaction) it resists oxidation. Similarly, naphthalene is not amenable to the author's process. F. H. L.

Separation of Ethylene from Benzene in Gas. E. Harbeck and G. Lunge (*Zeits. anorg. Chem.*, 1898, xvi., 26-50.)—In the ordinary analysis of coal or coke-oven gas, it is usual to estimate the "heavy hydrocarbons" by absorption with fuming sulphuric acid or bromine, making no distinction between the benzene and

the ethylene in spite of the fact that these substances are of very different value either for illuminating or heating purposes. The authors have investigated two methods of separating these hydrocarbons, the first depending upon the conversion of ethylene into ethane in presence of hydrogen and platinum black, the second on the nitration of the benzene. A full description of the preliminary experiments, the apparatus necessary, and the final calculations, is given in the original article; but it is too lengthy and replete with detail to be properly abstracted; the following cursory account, however, explains the principles underlying the two processes.

Conversion of Ethylene into Ethane.—A U-shaped tube, about 10 cm. long and 3 mm. in internal diameter, with capillary ends, is filled with 0·5 gramme of platinized asbestos (= 0·11 gramme of Pt), through an aperture in the base, which is afterwards sealed up. It is hung within a glass or metal beaker full of water or copper turnings, according to the temperature at which it is to be employed. A current of pure hydrogen is next passed through it for two hours at 100° C., and two hours in the cold to saturate the platinum black; and the apparatus is then ready for use. In one sample of the gas to be analysed, which must obviously contain an excess of hydrogen, the total amount of ethylene and benzene is determined by absorption in fuming sulphuric acid, the other constituents being estimated in the usual way. A second sample is freed from oxygen with alkaline pyrogallol, and led two or three times over the platinized asbestos at 100° C. The residue is treated with fuming sulphuric acid as before, which now absorbs the benzene only, the difference between the volume taken up before and after condensation thus giving the percentage of ethylene. As 1 volume of ethylene unites with 1 volume of hydrogen to form 1 volume of ethane, the proportion of the former ingredient may be more simply deduced from the contraction; but by operating in this manner it is impossible to determine also the hydrogen and the methane. Unfortunately, the process is not available for those many cases in which carbon monoxide is present in the original gas.

Direct Estimation of the Benzene by Nitration.—The sample of gas is passed through a 10-bulbed tube containing a mixture of equal parts by weight of pure strong sulphuric acid and fuming nitric acid (specific gravity 1·52), which converts the benzene into metadinitrobenzene, and removes the whole of the ethylene. The acid liquor is diluted with ice-cold water, neutralized with caustic soda (also in presence of ice), the bulk of the dinitrobenzene collected on a filter-paper (if there be sufficient of it precipitated to be worth filtering), and washed till free from acid. The filtrate and washings are made up to some convenient volume, and an aliquot portion is extracted twice with ether. The solvent is distilled off, the residue dried in a current of air, dissolved in fresh anhydrous ether, mixed with the rest of the product, the solution filtered, again evaporated, and the solid matter dried at 70° or 80° C. (or over sulphuric acid in vacuo) and weighed. The precipitate thrown down on neutralization is quite pure and without odour; that extracted by means of the ether is apt to be contaminated with mononitrobenzene; but the melting-point of the whole is generally about 86·5° C. (instead of 90° C.).

The reaction is perfectly quantitative; the products formed by the action of the acids on ethylene remain in the aqueous liquid, and do not affect the purity of the dinitrobenzene. Nevertheless, as the process is somewhat tedious and requires a

complicated apparatus, it should only be resorted to for specially important analyses as a check on the former method.

To convert the weight (N) of dry dinitrobenzene in grammes into the percentage by volume (V) of moist benzene vapour in moist gas at the temperature $t°$, and pressure b mm., the following formula may be used: s is the proportion of benzene plus ethylene, W that of the hydrogen in the original gas, and e the tension of aqueous vapour at $t°$ C.

$$V = 98{\cdot}50564 \times \frac{N(1 + 0{\cdot}00367t)(100 - s)}{W(b - \frac{31}{40}e)}.$$

F. H. L.

Use of Lead Carbonate in Analysis. G. Morpurgo. (*Giorn. di Farm. di Trieste*, 1897, ii., 355; through *Chem. Zeit. Rep.*, 1898, 19.)—The author recommends the use of freshly-precipitated lead carbonate in all cases where the acetate is usually employed, *e.g.*, for the removal of coloring-matter, acids, tannins, etc., from complex solutions. The moist carbonate only requires shaking with the liquid, does not dilute it, while the minute trace of lead which passes into solution can be easily removed by a small crystal of sodium sulphate. F. H. L.

Oil of Basil. J. Dupont and Guerlain. (*Bull. Soc. Chim.*, 1898, xix., 151-154.)—Two essences are known by the name of basil—one collected in the South of France and in Germany, having a sweet characteristic odour; the other imported from Reunion, being marked by a strong smell of camphor, which partly masks the characteristic odour. Moreover, the former is lævo-rotatory, the latter dextro-rotatory.

Dumas and Peligot (*Ann. Chim. Phys.*, lvii., 334) extracted from oil of basil a crystalline inodorous product, which they considered to be a hydrate of terebenthine $C_{10}H_{16} + 3H_2O$. The authors, however, have not been able to find any trace of this substance in two samples of the French essence.

The French oil examined by them was an oily yellow liquid with a specific gravity of 0·9154 at 15° C. and a rotation in a 100 mm. tube of $-7{\cdot}40°$. Four-fifths of the oil distilled over between 190° C. and 220° C., and the distillate was further fractionated into two main portions boiling at 195° C. to 200° C. and 205° C. to 215° C. respectively. The former, constituting nearly 60 per cent. of the essence, was an oily liquid, which was identified as linalol ($C_{10}H_{18}O$) by its composition and chemical and physical properties. The fraction boiling at 205° to 215° had the odour, chemical and physical characteristics of *p*-methoxy-allyl-benzene, the chief constituent of oil of tarragon.

A sample of Reunion oil examined by the authors was also found to contain *p*-methoxy-allyl-benzene, but no linalol, a fact confirmed by Bertram and Walbaum (*Arch. der Pharm.*, February, 1897), who found their sample to contain 60 per cent. of that compound and a small quantity of a dextro-rotatory camphor. The results of their analysis of a specimen of German oil showed a close agreement with those obtained by the authors in the case of French oils, and confirmed their conclusions as to the presence of linalol in the European essences and of camphor in the Reunion oil.

C. A. M.

Examination of Rose-Oil. P. N. Raikow. (*Chem. Zeit.*, 1898, xxii., 149.)—The present author is unable to corroborate the figures previously quoted (ANALYST, xxiii., 12) as characteristic of true rose-oil, and he does not consider Dietze's specification of much value. His own results are shown in the subjoined table. The samples are undoubtedly genuine, many of them having been extracted by himself from different varieties of the plants cultivated in different parts of the rose-growing districts. Nos. 1, 2, and 3 are mixed oils, made from red and white roses (as it is the custom to do with marketable specimens); 4 is from red roses alone (*R. centifolia*); 5 from inferior kinds of red flowers; 6 and 7 are the favourite and expensive "green rose-oils"; 8 is from Seraphimoff and Co., of Kazanlik, said to be the same as that examined by Dietze, who gave it an acid number of 1·2 and a saponification number of 9·2. The two samples of geranium-oil are from König and Co., of Leipzig-Plagwitz; the first is called "Ol. Geranii Turkicum rect. alb.," the second "Ol. Geranii Gallic. 1A." The specific gravities of the rose oils were determined at $\frac{27{\cdot}5^\circ\ \text{C.}}{15{\cdot}0^\circ}$, except No 8, which was at $\frac{27{\cdot}5^\circ\ \text{C.}}{17{\cdot}5^\circ}$; those of the geranium-oils were observed both at 27·5° and at 15° C. The optical examination of the rose-oils was carried out in a 100 mm. tube at 25° C.; that of the geranium-oils at 19° C. The solidifying-point is the temperature at which the first crystals of stearoptene were deposited. The acid and saponification numbers are nearly all the mean of two or more tests; the ratio in the last column is that between the acid and the ester number.

F. H. L.

The author concludes that the "constants" relied on by Dietze are not sufficiently precise to allow of the certain detection of adulteration.

On the Precipitation of Proteids. H. Schjerning. (*Zeit. anal. Chem.*, 1897, xxxvi., 643-663.)—The fact that ash-free proteids behave in a different manner from

those containing ash led the author to make experiments on the effect of adding salts to different precipitating reagents. It was found that the addition of various quantities of a 10 per cent. solution of calcium chloride did not interfere with the precipitation of proteid matter by stannous chloride. On the other hand, the precipitates obtained with lead, iron, or aluminium acetates gradually decreased as more of a 10 per cent. solution of calcium acetate was added. From this the conclusion was arrived at that in the case of the tin precipitate a sort of double salt with two basic radicles but only one acid was probably produced.

To determine the influence of salts containing a different acid radicle to that of the precipitating salts a similar series of experiments was made with a 0·4 per cent. solution of disodium phosphate. Up to a certain point the addition favoured the precipitation, but when added in excess had a disturbing effect. The reactions taking place were probably as in the equations:

$$2\text{Alb.Pb.CH}_3\text{COO} + \text{Na}_2\text{HPO}_4 = (\text{Alb.Pb})_2\text{HPO}_4 + 2\text{CH}_3\text{COONa} \text{ or}$$
$$2\text{Alb.Pb.CH}_3\text{COO} + \text{Na}_2\text{HPO}_4 = (\text{Alb})_2\text{Pb} + \text{PbHPO}_4 + 2\text{CH}_3\text{COONa}.$$

In applying this to the method of separating proteids the solutions of the precipitants were of the same strength as given in the *Zeit. anal. Chem.*, xxxv., 286, and whenever the proteid solution contained little or no phosphate the phosphate solution was added in the proportion of 20 c.c. to 6 c.c. of the lead acetate solution or to 0·8 gramme of ferric acetate and 40 c.c. of dilute acetic acid (15 c.c. of 40 per cent. in 1 litre). Care was taken that the proteid solution did not contain in 10 c.c. more nitrogen than corresponded to about 5 c.c. of decinormal acid.

The following table gives the results obtained with various proteid solutions. A cross indicates that the determination could not be made on account of the liquid not filtering clear, or, in the case of the ferric acetate, owing to the iron not completely precipitating on boiling:

	Solution.	Stannous Chloride. Without $CaCl_2$.	Stannous Chloride. With $CaCl_2$.	Lead Acetate. Without Na_2HPO_4.	Lead Acetate. With Na_2HPO_4.	Ferric Acetate. Without Na_2HPO_4.	Ferric Acetate. With Na_2HPO_4.	Normal Uranium Solution.	Precipitation with $MgSO_4$ + Acetic Acid.
Malt I.	100 grammes in a litre	8·5	8·9	18·0	20·6	+	31·9	41·8	19·9

* A very old sample.

From comparison with the results obtained with the malt-extract the author considers that there are two kinds of "albumin" present in milk. He divides the precipitated proteids in the following way, and adds, in a subsequent note, that the names "albumin," etc., are only to be regarded as a provisional nomenclature, indicating to some extent the characteristics of the substances.

a = Albumin I. = the tin precipitate.
b = ,, + albumin II. + denuclein = the lead precipitate.
c = ,, + ,, + ,, + propeptone = the iron precipitate.
d = ,, + ,, + ,, + ,, + peptone = the uranium precipitate.
e = ,, + ,, + propeptone = the magnesium sulphate precipitate.

Calculating the results from this, the substances were found to have the following composition:

	Malt Extract.		Egg-Albumin.		Milk.		Witte's Peptone.	Liebig's Peptone.	Liebig's Meat Extract.	Diastase.	Urine.
	I.	II.	I.	II.*	I.	II.					
Albumin I. ...	8·9	9·9	89·2	91·5	82·6	80·1	2·7	13·9	10·7	36·9	1·4
Denuclein ...	11·7	10·2	1·2	1·2	1·7	0·8	8·0	9·2	10·2	20·7	1·7
Albumin II. ...	—	—	1·9	1·5	7·9	11·0	48·5	33·2	0·0	22·8	0·0
Propeptone ...	11·3	12·9	3·9		1·6	1·1			6·1		0·7
Peptone ...	9 9	11·1	2·7	0·0	0·0	0·0	0·0	0·0	11·4	5·5	0·0
Total ...	41·8	44·1	98·8	94·2	93·8	93·0	59·2	56·3	38·4	85·9	3·8

The author remarks that the fact that he finds no true peptone, but only propeptones, in either Witte's or Liebig's peptones is in accordance with the results of König and Bömer; but, on the other hand, he differs from them in finding a large quantity of peptone in Liebig's meat extract (*cf.* ANALYST, xxi., 17). C. A. M.

The Classification of Proteids. A. Wroblewski. (*Berichte*, 1898, xix., 3045-3052.)—The author defines proteids as bodies which on complete decomposition with acids yield as final products ammonia, nitrogenous organic bases (such as lysine, arginine, etc.), and amido acids (such as leucine, tyrosine, etc.). Hence, protamines, which yield no amido acids on decomposition, cannot be classed with the proteids, although closely allied to them. Probably peptones, also, do not comply with the definition, though, for want of more definite knowledge, they may be grouped with their mother-substances, the albumoses.

In the subjoined scheme of classification the proteids are divided into three main groups: I. Albuminous bodies (Eiweissstoffe); II. Compound albuminous bodies (Zusammengesetzte Eiweissstoffe); and III. Albuminoid bodies (Eiweissähnliche Substanzen).

To the first group belong proteids which are closely related to fresh or coagulated white of egg; they contain sulphur in their molecule. *Albumins* are soluble in water. *Globulins* are insoluble in water, but soluble in dilute saline solutions. *Albumins soluble in alcohol* all dissolve in dilute spirit of wine, and many of them in strong spirit. *Albuminates* are formed by the action of alkalies on albumins. They are insoluble in water, but readily soluble in alkalies. *Acid albumins* are produced by the action of acids on albumins, and are soluble in very dilute acids or

alkalies. *Coagulated albumins* are the products of the coagulation of albumins by heat or by enzymes, and are marked by their great insolubility.

The second group comprises proteids whose molecule consists of an albumin group, and another group often of a non-proteid nature. Thus, in *hæmoglobins* there is a coloring-matter group; in *glyco-proteids* a carbohydrate group; in *nucleo-albumins* a nuclëin group; and in *nuclëins* a nucleic acid group.

The third group is subdivided into three classes: (1) Structural substances (Gerüstsubstanzen); (2) Albumoses and peptones; (3) Enzymes.

In the first class are *keratins*, constituents of horn. They contain much sulphur, are only with difficulty attacked by pepsin and trypsin, and on decomposition yield much tyrosin. *Elastins* are contained in the cartilaginous tissues. They are hardly soluble in reagents, contain little sulphur, and on decomposition yield but little tyrosin. *Collagenes* contain very little sulphur, and do not give aromatic amido-acids as decomposition products.

Albumoses and peptones, constituting the second class, have much smaller molecules than the albuminous bodies. By virtue of their toxic properties some of the albumoses are closely related to the enzymes.

The *enzymes*, grouped in the third class, might be further divided in accordance with the conditions of their greatest activity. Thus, some work best in acid solution, others in alkaline solution. Among the former are: pepsin, ptyalin, diastase, invertin, myrosin, and emulsin; whilst representatives of the latter are trypsin, steapsin, and urase.

PROTEIDS.

GROUP I. Albuminous Substances.	GROUP II. Compound Albuminous Substances.	GROUP III. Albuminoid Substances.		
		Class 1. Structural substances. (Gerüstsubstanzen).	*Class* 2.	*Class* 3. Enzymes.
1. Albumins: Egg albumin Serum albumin Lact-albumin Muscle albumin Plant albumin Etc. 2. Globulins: Egg globulin Serum globulin Lacto-globulin Fibrinogen Myosin Plant globulins Vitellin (?) Etc. 3. Albuminous substances soluble in alcohol: chiefly of vegetable origin. 4. Albuminates. 5. Acid albumins: Syntonin and the like. 6. Coagulated albuminous substances: Fibrin Paracasein Coagulated white of egg.	1. Glyco-proteids: Mucins Mucoids. 2. Hæmoglobin. 3. Nucleo-albumins. 4. Caseins: Of cows' milk Of human milk. 5. Nuclëins. 6. Amyloids. 7. Histones (?)	1. Keratins. 2. Ela-tins. 3. Collagenes: Collagene, Glue, and the like.	Albumoses and Peptones.	1. Proteolytic: Pepsin Trypsin Papayotin and the like. 2. Amylolytic: Diastase Invertin and the like. 3. Fat-decomposing enzymes: Steapsin and the like. 4. Glucoside decomposing enzymes. 5. Amide decomposing enzymes: Urase and the like. 6. Coagulating enzymes and the like: Rennet and the like.

C. A. M.

Taka Diastase. J. Takamine. (*Amer. Journ. Pharm.*, 1898, lxx., 137-141.)—In Japan and other Asiatic countries certain fungi are used for the production of diastase. That used in Japan belongs to the genus *Aspergillus*, and is termed *Moyashi*. This is specially cultivated on sterilized wheat bran or other suitable material, and when mature is dried, and the spores separated by shaking or sifting; the product thus obtained is called *Taka-moyashi*, and can be preserved indefinitely. For the manufacture of diastase for commercial purposes, wheat bran is moistened with water, steamed, and, after cooling to below 40° C., is mixed with a little Taka-moyashi, and spread in a layer in a room similar to a malt-floor, where the temperature is maintained at about 25° C., and the humidity at about 80 per cent. Within forty to fifty hours the diastatic power of the mass reaches its maximum, and further growth is checked. The mass is known as *Taka-Koji*, and can be used in the green or dried state. The diastase it contains is soluble in water, and an aqueous extract of the Taka-Koji, concentrated in vacuo to a syrup, has from eight to ten times the diastatic power of malt extract of similar consistency.

The diastase can be precipitated from this aqueous extract by the addition of alcohol, and when separated by means of centrifugal force and air dried is a non-hygroscopic yellowish-white powder, readily soluble in water, and capable of converting over one hundred times its weight of starch in ten minutes. By further purification by re-precipitation or otherwise, its diastatic power, which is exceedingly stable, can be still further increased. C. A. M.

A Simple and Accurate Method of Testing Diastatic Substances. J. Takamine. (*Amer. Journ. Pharm.*, 1898, lxx., 141-143.)—This is based on the great stability of Taka-diastase (see preceding abstract), which does not lose its diastatic power with keeping, as the author finds to be the case in the diastase isolated from malt.

The exact diastatic capacity of a quantity of Taka-diastase is determined once for all by Lintner's or Junk's method (ANALYST, xxi., 122), and that of any substance under examination compared with the standardized sample, and expressed in any terms desired.

Eight glass cylinders, holding about 150 c.c., are placed in water warmed to about 40° C., and into each is poured 100 c.c. of 5 per cent. starch paste. In the first glass is placed 1 c.c. of the saliva or other liquid to be tested, whilst the other seven cylinders receive successively increasing quantities of a freshly-prepared 1 per cent. solution of the standard Taka-diastase, commencing with 1 c.c. in the second cylinder, and ending with 7 c.c. in the eighth. The contents are stirred until the starch becomes liquid, and a drop from each is then removed to a white tile, where it is mixed with 1 drop of a solution of iodine, prepared by dissolving 1 gramme of iodine and 2 grammes of potassium iodide in a little water, and making up to 120 c.c. The drops, when spread out on the tile, with the finger form a colorimetric scale, ranging from blue to purple and reddish-brown, and the colour given by the substance in the first tube is readily matched. C. A. M.

INORGANIC ANALYSIS.

Estimation of Tin in Stannic Salts. **A. Fraenkel and J. Fasal.** (*Mitth. k.k. Tech. Gew. Mus.*, 1897, 227; through *Chem. Zeit. Rep.*, 1898, 11.)—An amount of the stannic salt containing 0·2 to 0·4 gramme of tin is treated with a few drops of strong hydrochloric acid, and 0·5 to 1 gramme of aluminium wire is added. The whole is warmed gently for about half an hour, or until hydrogen is given off briskly, and a fresh piece of wire does not become coated with tin, thus showing that decomposition is complete. Ten c.c. of strong hydrochloric acid are next introduced, and the flask is heated for fifteen minutes till all the metal is dissolved and no more gas is evolved. The solution of stannous chloride is then mixed with Rochelle salt, made faintly alkaline with sodium bicarbonate, and titrated with iodine; or if the greater part of the free acid only is neutralized, Fraenkel's potassium bichromate method may be adopted. The results are slightly too low. F. H. L.

Separation of Beryllium from Aluminium. **F. S. Havens.** (*Zeits. anorg. Chem.*, 1898, xvi., 15.)—This process is identical in principle with that already described by Gooch and Havens for the separation of iron from aluminium by means of ether and hydrochloric acid (ANALYST, xxii., 194); but the details of the operation have been slightly modified, and it is now preferably carried out in the following manner: Fifteen c.c. of the aqueous solution of the mixed chlorides of aluminium and beryllium, containing about 0·2 gramme of the corresponding oxides, are placed in a covered platinum basin, and suspended within a larger vessel through which a current of cold water is constantly passing. The liquid is saturated at 15° C. with gaseous hydrochloric acid, 15 c.c. of ether are added, and the whole is saturated with gas once more. The insoluble aluminium chloride is collected and treated exactly as before; the filtrate, which is allowed to run directly into a platinum crucible, is slowly and cautiously evaporated till all free acid is driven off, then mixed with a little nitric acid to convert it into nitrate, evaporated again, and finally ignited, first at a low temperature and afterwards over the blowpipe. The author states that if the beryllium chloride contains no free HCl when the nitric acid is dropped in, the platinum will not be attacked; but the residue must not be heated more than necessary, lest part of the chloride volatilise. The beryllium can also be determined by removing the excess of HCl and then precipitating with ammonia. The results are sufficiently accurate: calculated as Al_2O_3, the aluminium is from 0·1 to 0·8 per cent. too low; the BeO from 0·4 to 0·8 per cent. too high.

F. H. L.

Use of Metallic Sodium, Magnesium and Aluminium in Blowpipe Analysis. **W. Hempel.** (*Zeits. anorg. Chem.*, 1898, xvi., 22.)—The utility of ordinary blowpipe analysis is somewhat restricted by the difficulty of exposing the substance under examination to a satisfactory reducing flame. This may be overcome in the following manner. A very small, clean fragment of sodium (the size of a grain of millet) is laid on a piece of filter-paper about 4 square centimetres in area, and pressed out with an oily knife until it is quite thin and pliable. The

powdered sample is placed in the middle, and the whole rolled up into a cylinder so that the paper forms a double layer all round. The cylinder is wrapped round with a close spiral of iron binding-wire, the excess of paper cut off, and the cartridge approached to the edge of a Bunsen giving a reducing flame till the paper catches fire. Immediately the reaction is over, the wire is thrust into the centre of the flame to protect the mass from oxidation, and gradually lowered towards the orifice of the burner until it is cooled by the current of gas. The residue is shaken out of the wire and extracted with water in an agate mortar to dissolve the caustic soda. When this has been removed, the insoluble portion can be examined as usual, any reducible metals which the original body contained being present in considerable amount. Silicon and boron will also be found in the elemental state mixed with some carbon from the paper; the residue should then be treated with hydrochloric acid, washed with water, ignited on foil till the carbon is burnt off, when a sufficient proportion of the silicon and boron will still be left unoxidized to respond to the ordinary tests.

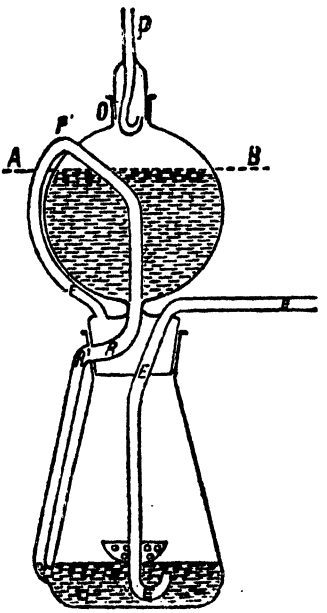
The metallic sodium should be kept in an air-tight bottle rather than under petroleum; and if care be taken not to employ too much of it, there is no danger of an explosion. If it be desired to recover a larger quantity of the reduced matter, the mixture may be diluted with common salt, and the reaction effected in an iron crucible. (Silicates may quickly be opened up in this way.)

As the presence of sodium salts hinders the recognition of other metals by their flame tests, a further portion of the sample may be mixed with powdered aluminium or magnesium, wrapped in paper and treated as above; but owing to the infusibility of the earths the reduction is not so complete as with sodium. F. H. L.

The Analysis of Crude Sodium Sulphide. F. Jean. (*Jour. Pharm. Chim.*, 1898, vii., 170-172.)—Ten grammes of the sulphide rapidly broken into large pieces, in order to obtain an average sample, are dissolved in a little water, and the solution after removing the insoluble matter by filtration, made up to a litre. Ten c.c. of this solution are titrated with decinormal iodine with starch as indicator. The volume used corresponds to the sulphide, sulphur in excess, and thiosulphate.

To a second portion of 10 c.c. a solution of ammonium sulphate (6·7 grammes per litre), is added, the same volume being taken as was used of the iodine solution in the preceding titration. After the addition of 30 c.c. of water the liquid is distilled, and the ammonia liberated by the sodium monosulphide received in 20 c.c. of decinormal acid. This is subsequently boiled to remove sulphuretted hydrogen, and titrated with decinormal alkali with turmeric as indicator. Each c.c. of decinormal acid neutralized by the ammonia corresponds to 0·0039 gramme of sodium monosulphide.

The residual liquid in the distilling-flask is titrated with decinormal iodine when cold, each c.c. used corresponding to 0·0079 gramme of sodium thiosulphate. The difference between the amount of iodine solution required here and that used in the first titration corresponds with the sulphur of the sulphides and polysulphides, which may be expressed as sodium monosulphide by multiplying the number of c.c. by 0·0039. The quantity thus calculated is always in excesss of that obtained by the



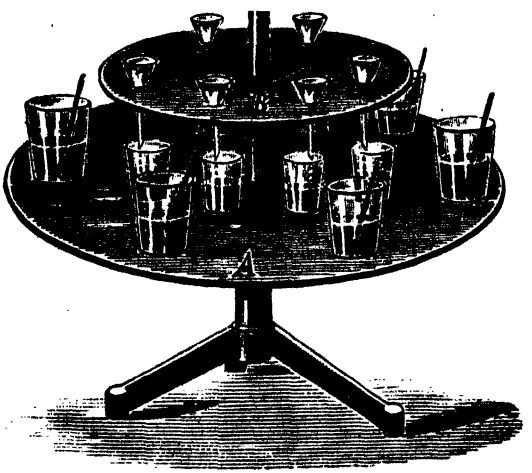
distillation with ammonium sulphate, owing to the excess of sulphur in the polysulphides being included in the monosulphide. This excess is therefore calculated into sulphur (100 of sodium sulphide = 41 sulphur).

If the sample contained only monosulphide the results obtained by the distillation with ammonium sulphate and by the titration with iodine would agree. The result obtained by titrating the sulphide with an ammoniacal solution of zinc is the same as that obtained in the iodine titration (making a deduction for the thiosulphate) since the sulphur of the polysulphides acts upon the zinc like the monosulphide.

In the course of their experiments on this method the authors have established the following facts: (1) When a solution of sodium monosulphide is boiled with an excess of ammonia, part of the sulphur is volatilized in the form of ammonium sulphide; and (2) when a solution of sodium thiosulphate is boiled with an excess of ammonium sulphate there is a liberation of ammonium sulphide and a deposit of sulphur; but this decomposition does not take place in an alkaline liquid, or under the conditions described above. C. A. M.

APPARATUS.

Apparatus for the Valuation of Manganese Peroxide. M. Nothomb. (*Chem. Zeit.*, 1898, xxii., 80.)—This apparatus may either be used for the purpose indicated or for the estimation of carbon dioxide. It is comparatively small, and when fully charged weighs only about 80 grammes. The glass stopper of the flask serves also as a stopcock, opening or closing communication between R and R^1 according as it is revolved in the neck of the flask. The latter contains a small quantity of dilute sulphuric acid, but not enough to touch the perforated receptacle carried by the tube E. Into the acid is put a weighed amount of manganese peroxide, and a few crystals of oxalic acid are laid in the basket. The stopper is then inserted in such a position that R and R^1 are not connected, strong sulphuric acid is poured into the bulb to the height shown, and the whole weighed. Connection is next made between R and R^1 till the oxalic acid is covered with liquid; and when the reaction has ceased, dry air is blown in through E to drive out the carbon dioxide.



The lower part of the tube F^1 inside the bulb is of course not joined to R, as might be imagined from the illustration given herewith. F. H. L.

A New Measuring Pipette. O. Bleier. (*Chem. Zeit.*, 1898, xxii., 59.)—With reference to the illustration of his pipette on p. 55 of this volume, the author notes that for convenience sake the distance between each bulb should be a trifle greater

than there shown—in fact, that each constriction should be a short tube—as otherwise, although the capacity of the apparatus between each graduation may easily be determined, it will probably work out to some uneven number of cc.s, thus depriving the pipette of much of its practical simplicity.

A modified form of the arrangement, which will be found very useful, especially for measuring large volumes of water, as in diluting liquids or making up standard solutions, may be prepared by constructing the bulbs of different sizes. For instance, the graduated portion *a*—*b* may contain 25 c.c. ; *b*—*c*, 25 c.c. ; *c*—*d*, 50 c.c. ; *d*—*e* 100 c.c. ; *c*—*f*, 200 c.c. ; so that by suitable manipulation any quantity of water can be measured with perfect accuracy. In this manner the use of graduated flasks, which are of necessity marked high up in the neck, can be avoided ; and a standard solution may be prepared in a much larger vessel by weighing the solid, calculating the proper amount of water, and adding it by means of the measuring burette, when, as the vessel need only be half full, the liquid can be shaken satisfactorily till solution is effected.

F. H. L.

A Convenient Filter-stand. H. Faber. (*Chem. Zeit.*, 1898, xxii., 39.)—The construction of this stand is sufficiently explained by the diagram. The tables A and B are either fastened rigidly together so that they revolve simultaneously on the vertical axis C, or B may be carried by a shoulder on the socket rising from A, in order that by the insertion of a suitable number of washers underneath B, the distance between the two tables may be adjusted to suit different sized funnels and beakers.

F. H. L.

An Improved Asbestos Filter. A. Goske. (*Chem. Zeit.*, 1898, xxii., 12.)—The object of this improvement is to reduce the amount of asbestos necessary to ensure efficient filtration, so that while the filtrate is perfectly clear, yet the operation is not unduly prolonged. As will be seen in the accompanying cut, the hollow glass ball has two small holes in its upper part. It is covered with a layer of dry asbestos fibre about 5 mm. thick, then connected with the pump, and a sufficient quantity of asbestos powder previously suspended in water is poured over it in the same way as is done in preparing a Gooch crucible.

F. H. L.

THE ANALYST.

MAY, 1898.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

JAPANESE WOOD-OIL.

By J. H. B. Jenkins.

(*Read at the Meeting, March* 16, 1898.)

Japanese wood-oil (Chinese wood-oil, Tung-oil) is still so little known generally, that the results of the examination of a sample which recently came into the author's hands may be of interest. It is an oil of considerable viscosity, high density, and remarkable drying properties, and is produced from the nuts of the wood-oil tree (*Aleurites Cordata*) in Japan and China, where it is used in large quantities in painting and calking, and for many other industrial purposes. It is said to be extensively used in native medical remedies in virtue of its purgative, emetic, and very poisonous properties when freshly prepared.

For comparison with the results obtained from this sample, others are collated from an earlier sample examined by the author a year ago. Most of these latter results have already appeared in the *Jour. Soc. Chem. Ind.*, 1897, 193 and 195.* The following other references to work done on the oil may be useful: Cloëz (*Bull. Soc. Chim.*, xxvi., 286, and xxviii., 23); Davies and Holmes (*Phar. Jour.*, 1885, 634 and 636); Deering (*Imp. Inst. Jour.*, August, 1896, p. 303); De Negri and Sburlati (*Sc. Mon.*, September, 1897, p. 680).

	Present sample.	Earlier sample.
Specific gravity at 60° F.	0·9343	0·9385
Insoluble fatty acids	96·0%	96·4%
Unsaponifiable matter	0·63%	0·44%
Glycerin	10·6%	10·4%
Free fatty acids (calc. as oleic)	1·83%	3·84%
Viscosity at 60° F. (water takes 28 secs.) ...	858 secs.	1433 secs.
Solidifying point	below − 17° C.	below − 17° C.
Bromo-thermal rise (= $x°$)	21·4° C.	23·4° C.
Calc. iodine value ($x° \times 5·7$)	122·0	133·4
Calc. iodine value ($x° \times 7·0$)	149·8	163·8

* In the Analyst for February, 1898, p. 43, there is an abstract relating to Japanese wood-oil taken from German periodicals. With the exception of a couple of interpolations and errors, the particulars are derived wholly from the author's paper in the *Jour. Soc. Chem. Ind.* above referred to.—J. H. B. J.

	Present sample.	Earlier sample.
Iodine value (Hübl)	... 149·7	165·7
Saponification value (Mgms. KHO)	... 192	194
Specific temperature reaction ...	... 298	330
The insoluble fatty acids gave:		
Melting point	... 30–31° C.	37° C.
Bromo-thermal rise ($= x°$) ...	... 21·0° C.	22·1° C.
Calc. iodine value ($x° \times 5·7$) ...	... 119·7	126·0
Calc. iodine value ($x° \times 7·0$) ...	... 147·0	154·7
Iodine value (Hübl)	... 144·1	150·1

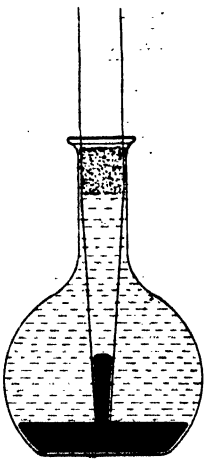
Viscosity.—The viscosity was taken with Redwood's instrument, through which the same quantity of water (50 c.c.) flows in 28 secs., and averages pure rape-oil in 470 secs., at 60° F.

Specific Temperature Reaction (Maumené Test).—The peculiar property of the oil of solidifying in contact with sulphuric acid makes it necessary to largely dilute it before this test is applied. When the acid is added to a solution of 10 grammes of Japanese wood-oil in 40 grammes of diluent, it becomes for a time semi-solid, but soon thins again and permits the maximum temperature to be recorded. A thin mineral oil was first tried as diluent, and an allowance made for the fraction of heat due to it. Mineral oils, however, heat very slowly as compared with fatty oils on treatment with the acid, and such a correction was open to suspicion. For this reason olive-oil was adopted instead, and, although the correction-figure was larger, it was thought to be more satisfactory. The figures given above are calculated from experiments made on 10 grammes of sample diluted with 40 grammes of olive-oil.

Valenta's Test.—The temperature of turbidity with glacial acetic acid was 44° C. The earlier sample gave 47° C.

Elaïdin Test.—In this test the oil darkened considerably. Examined after twenty-four hours, there was an oily upper layer on a more solid portion on the bottom; when stirred up the whole would slowly flow.

Becchi's Argentic Nitrate Test.—A quarter hour's heating with the reagents produced no appreciable deepening of colour. This is different from the earlier sample, which gave a deep reddish-brown coloration.



Halphen's Test (*Revue de Chim. Ind.*, February, 1898).—In this test the presence of cotton-seed oil is indicated by the production of a red coloration on heating the suspected oil with amyl alcohol and CS_2 containing some dissolved sulphur. Each of the samples of Japanese wood-oil when tested thus gave negative results. The fact that one of the samples gave the Becchi reaction strongly, but no coloration with the Halphen test, is interesting.

Oxidizing and Drying Properties.—Four grammes of the oil were exposed in the boiling-water oven in a shallow porcelain dish 7 cm. diameter, and weighed after successive hour's exposures. At first there was a slight loss, probably due to moisture in the oil; the average gain of weight during the first eight hours' exposure was 0·26 per cent. per hour. In six hours the surface was entirely covered with a crinkled skin. The earlier sample, under these conditions, gained during four hours exposure at the average rate of 0·36 per cent. per hour, and was covered with a crinkled skin in two hours. A sample of linseed-oil similarly exposed had no sign of

any skin on the surface at the end of eight hours, and the average gain per hour was 0·10 per cent.

Optical Properties.—The sample did not cause any rotation of polarized light. It had very high refractive power at 19° C.; and with the sodium light, its refractive index was 1·503.

Polymerization on Heating.—The oil was heated out of contact with air. The apparatus used (*vide* sketch) was a small flask into the neck of which a glass tube was ground. The tapering lower end of this tube reached below the surface of some mercury at the bottom of the flask. The rest of the flask was completely filled with the oil. During the expansion of the oil a little of the mercury is forced up the central glass tube, but air is rigidly excluded from the oil during its exposure to the heat. The flask was heated in a glass air-bath. The oil was in this way heated first for two hours at 200° C. but remained liquid, then the temperature was raised to 250° C. and kept at that for another couple of hours, during which time the oil thickened and the minute bubbles of gas, which had been arising through the oil for some time, were now held entrapped *en route*. When cold, the oil was found to have been converted into a sticky elastic jelly. The earlier sample of Japanese wood-oil, when similarly treated, yielded a hard, dry, elastic solid. There was no darkening of colour in either case and the products remained clear. There was a decrease of solubility of the oil in all ordinary oil-solvents in proportion as this polymerization change had taken place. This peculiar property was noticed by Cloëz, who also found that exposure to direct sunlight, without any heating, was sufficient to solidify the oil in a few days. Possibly the great difference in viscosity which is noticed in the two samples may be due in some degree to a partial polymerization of one of the samples.

Action of Bromine and Iodine.—The iodine value of the oil was determined by the Hübl method, and the bromo-thermal test applied in the way laid down by Hehner and Mitchell (ANALYST, July, 1895). A year ago these two tests were used comparatively by the author in the examination of a variety of fatty oils, including Japanese wood-oil. It was then found that the remarkable constancy of ratio between the temperature rise on bromine treatment and the iodine value which exists for fatty oils, did not extend to the Japanese wood-oil. Thus, whilst the factor 5·7 applied to the thermal rise gave the iodine value for all the other fatty oils examined (excluding "blown" oils), the factor 7·0 had to be applied for the Japanese wood-oil. It is found that this peculiarity exists also with the present sample of the oil, as well as with the fatty acids from each. (By an error of calculation, it has been stated, *Jour. Soc. Chem. Ind.*, 1897, 193, that this anomaly disappears when the fatty acids are examined; this, however, is not so.) The fact that the heating on bromine treatment is not so great as one would expect from the iodine value suggests that the action of the bromine on the oil is not so extensive as that of the Hübl reagent; but this is hardly so, as the bromine *absorption* value of the oil is not low as compared

with the iodine value. The cause will probably be found in a peculiarity of chemical structure of the fatty acids.

In trying to get some light on the anomaly, the author tried the effect of a chloroformic solution of iodine on the oil. A couple of grammes of the oil were dissolved in 5 c.c. of chloroform, and 5 c.c. of a saturated solution of iodine in chloroform were added with agitation, when the whole was rapidly converted in a jelly, the stiffness of which was proportional to the amount of oil taken. The amount of iodine in the 5 c.c. of chloroform is quite inadequate to saturate the oil. In the earlier sample of Japanese wood-oil 1 gramme of the oil was sufficient to produce a jelly in a couple of minutes, but the present sample is not so sensitive; 2 grammes of it produce a jelly in a couple of hours, and a solution of 4 grammes instantly jellifies on treatment.

This peculiarity has not been noticed with any other fatty oil. A solution of iodine in other solvents produces the same effect. If a saturated solution of iodine in $CHCl_3$ or CS_2 be dropped upon the oil, it immediately solidifies it. Bromine, whether in solution or otherwise, has no similar action on the oil.

The melting-point of the fatty acids from the later sample was not very definite. The solidified fatty acids have a peculiar wavy or rosette-like appearance.

The author is indebted to Messrs. Horner and Sons, of Mitre Square, Aldgate, for the later sample.

Discussion.

The President having invited discussion:

Mr. Hehner said that, owing to the courtesy of Mr. Jenkins, he had been able to make some experiments on a small sample of this oil. He had independently found the remarkable gelatinization referred to, which was a most characteristic property of this oil. This oil was quite different in constitution from any ordinary oil which gave figures of this kind. From the high iodine number it was quite plain that the oil must contain a highly unsaturated acid, in this respect approaching linseed-oil. Linseed-oil formed a hexabromide which was exceedingly insoluble, a proof that linolenic acid was present, and one would expect that this Japanese wood-oil, from its high iodine number, also contained a considerable quantity of linolenic acid. But absolutely no insoluble hexabromide was formed, showing that it must contain a different unsaturated acid from any of those known at the present time. The figures for rise of temperature in the bromine absorption test really applied only to ordinary oils, and he hardly considered this an ordinary oil as hitherto known to chemists. The factor, therefore, failed; but it failed also in every other unsaturated compound in which the acid was other than oleic, linolic, or linolenic acid. This was another proof that Japanese wood-oil contained an acid which was not one of the generally known unsaturated acids.

A TYPICAL NORTH-EAST LANCASHIRE RIVER.

By F. R. O'Shaughnessy.

(*Read at the Meeting, March* 16, 1898.)

Some time ago I had occasion to examine the water of the river Calder, a stream which flows through Burnley. The results of the analyses themselves are only what one would expect to find in a polluted water; but when the series is considered collectively, and in conjunction with the nature of the pollution taking place at different points along the stream, a few interesting points present themselves. Acting on the suggestion of our President at the last meeting, I thought that these points might not prove uninteresting to the members of the Society.

The stream rises on a moor, and the condition of the water here probably coincides with that of the Padiham drinking-water, the analysis of which is contained in sample No. 1 of the table. It flows for some distance through the open country, and then passes through the town of Colne. There there are a number of cotton factories, skin-dressing establishments, etc., and just below the town is the sewage-farm. About half a mile further on the Pendle water, which nearly equals the main stream in bulk, enters. Two miles farther on the stream passes the sewage-farms of Nelson and Brierfield. Lower down still on the bank Burnley sewage-farm lies, and a branch of the river which flows through Burnley enters. A couple of miles more and the stream runs through Padiham, a small town of about 15,000 inhabitants. In the centre of Padiham a brook enters, which consists largely of the refuse from a print-works and a large chemical works. Below Padiham another smaller brook enters similar to the last. A mile or so lower down there are two sewage-farms and a paper-mill, with some settling-tanks for purifying the refuse. The river then flows on through open fields, and receives the effluent from still another sewage-farm through the medium of one tributary, and the refuse from a print-works through a second tributary. Finally it disgorges itself in the Ribble at Thacking Hall.

In the table of analyses the Padiham drinking-water, which appears under No. 1, was analysed in order to give an idea of what a typical good water of the district was like.

Sample No. 2 was taken at a point on the moors about a mile or so from the source of the branch of the river selected. There the dark colour is due to peaty matter, the "total solids" are low, and the "loss on ignition" what one would expect in a peaty water. The "suspended matter" is very low, as is also its loss on ignition, showing that it probably is all derived from the bed of the stream. The lime, chlorine, and sulphuric acid are low, whilst the "oxygen absorption" and "free" and "albuminoid ammonias" are fairly high.

Sample No. 3 was taken below the first large town, viz., Colne, and gets the benefit of the effluents from two sewage-farms. There is a general rise in all the constituents, especially in the free and albuminoid ammonias. We note, however, a fall in the oxygen absorption, and, curiously enough, this corresponds with the trace of nitric acid found in this sample, which shows that oxidation must have taken place.

Sample No. 4 was taken at a point below the towns of Nelson and Brierfield, and the river above this point receives the effluents from their respective sewage-works as well as the two previously mentioned. There we note the immense rise in free ammonia, whilst the albuminoid ammonia falls slightly and the chlorine considerably. This latter fact is due to the entrance of the Pendle water, which is in fairly good condition.

Sample No. 5 was taken below Burnley sewage-farm, and the point where the branch of the stream which flows through Burnley enters. Here the oxygen absorption and free and albuminoid ammonia reach a terrible altitude. In the first four samples we note that the ratio between the loss on ignition of the total solids to the total solids is, roughly, about one-third. But in sample No. 5 this ratio falls considerably. This is in all probability due to pollution from manufacturing sources in the town of Burnley.

Between the points where samples No. 5 and No. 6 were taken there are no sewage-farms. At the same time, there is a considerable amount of water entering the river from brooks and small streams, and the diluting effect of this water is seen in the immense fall in free ammonia. On the other hand, these brooks, etc., consist largely of refuse from print works and chemical works, and their effect is seen in the rise in chlorine and sulphuric and total solids.

The whole of the samples from No. 2 to No. 6 were taken in succession on the same day. Sample No. 7 was not taken till the morning following, and hence is not strictly comparable with the other samples. Between the points where No. 6 and No. 7 were taken there are two sewage-farms and a paper-mill. We see that everything has fallen off but the free ammonia and sulphuric acid. The rise in the former is undoubtedly due to the effluents from the sewage-works. The latter is probably due in part to manufacturing sources, pollution from which, I have reason for believing, takes place pretty heavily during the night.

If we examine the ratio between the loss on ignition of the suspended matter and the suspended matter itself, the steady rise in this ratio as we descend the stream is very striking.

As an appended note to this paper, I would like to draw attention to the use of salicylic acid as a means of preserving a standard solution of sodium thiosulphate, a solution which is much used in water analysis. The figures in Tables I. and II. were obtained by Messrs. Richmond, Boseley and myself in our ordinary routine work by titrating the thiosulphate against 10 c.c. of standard permanganate.

A NEW FORM OF CONDENSER.

By Cecil H. Cribb, B.Sc., F.I.C.

(*Read at the Meeting, March* 16, 1898.)

The form of condenser with which Liebig's name is inseparably connected has served its purpose so well and has been in use for so long that it seems almost sacrilege to attack such a venerable institution. There can be no doubt, however, that theoretically it is most inefficient in proportion to its size, and that practically, in addition to being very cumbrous and heavy, it is in many other ways extremely inconvenient.

A number of other forms have from time to time been introduced, but up to the present not one of them has been at all largely adopted.

With regard to the efficiency of the Liebig condenser, the chemist whose laboratory operations are generally conducted on a small scale has but little reason to trouble. Provided condensation be complete, the actual amount of cooling water used is of little importance, but the absurd size of the present apparatus is a matter much more worthy of consideration. The great amount of bench-room taken up by condensers, and the expense involved in laying on water over large areas, renders it desirable that the space given up to distillation purposes should be as small as is conveniently possible. Any reduction in the size of the condensers must, to be of service, be accompanied by a corresponding increase in efficiency.

A theoretically perfect condenser should present to the vapour a cooled surface as large as possible, while the space into which the vapour has to pass should be as

small as possible consistent with its offering only a very low resistance to the passage of vapour into it. In any case, whatever its absolute or relative size may be, it should be of such form and disposition that the stream of incoming vapour can drive the air before it, so that the major part of the condensing space is filled with the pure vapour.

The Liebig condenser is obviously far from fulfilling these conditions; the worm condenser has nearly all the bad points of the Liebig, of which it is really only a coiled form. The spherical condensers also, now becoming so popular on account of their smallness, are as a rule made with the condensing chamber much too large.

The general plan of the form now exhibited is shown in the accompanying sketches. The vapour enters through the tube A into the condensing space B between the two tubes, C and D; after condensation the distillate passes out through E. The cooling water passes down the tube F into the interior of C, which it fills, and, running over the rim at the top, passes in a thin stream down the outside of D, finally flowing away through the escape pipe G. When used as a reflux condenser, the vapour, of course, passes up through E. After allowing the liquid to get into full ebullition, so that the air is driven out of the condensing space, the mouth of A may be completely closed with a cork, thus avoiding even the possibility of loss with volatile liquids such as ether. The apparatus must obviously always be used in one and the same position, *i.e.*, with its axis vertical. This is a distinct advantage, because it is very easily so supported, and because, when thus disposed, it takes up a minimum of space on the bench. An absolutely vertical position, however, is not necessary. It is preferable that the top of the condenser should slope, if at all, towards the flask or retort from which the liquid is being distilled. To obtain the greatest possible efficiency in working, special steps should be taken to ensure the even distribution of the water over the outside of the condenser, as the adhesion between the water and the glass or metal, and the surface tension of the water itself, are reduced to a minimum at high temperatures, so that the cooling water tends to run in narrow streams outside D, instead of spreading out. This is easily remedied by covering D externally, either partially or entirely, with some absorbent material, such as blotting-paper or linen (the latter as a permanence is to be preferred). In addition to this a cork I (Fig. 1), with a number of vertical grooves cut round its outside, is inserted into the mouth of C. The cork is perforated for the cold-water supply tube F, and the water leaves the interior of C by the grooves in the cork, thus getting well distributed round the outside of the condenser. This little device has

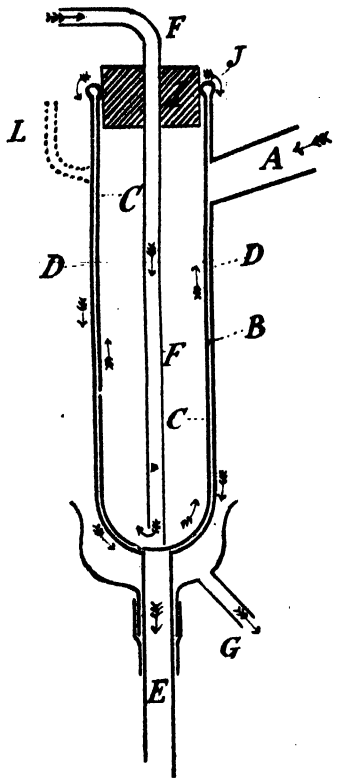

FIG. 1.

the further advantage of preventing any water getting spilt if the condenser receives a sudden knock or jerk whilst in action. With metal condensers the cork may be replaced by a metal disc H (Fig. 2) attached to the cold-water supply tube, and arranged so as to leave space either below it (as in the sketch), or outside it for the water to flow out of the cup on to the exterior of D.

To ensure the utilization of the whole available cooling surface, a wire or band of metal K (Fig. 2) may be coiled spirally round the interior of the condensing space, thus converting it into a flat spiral channel.*

Efficiency.—This may be treated both from a theoretical and from a practical standpoint.

Theoretically it is obvious that the new form has many points of superiority over the Liebig, the worm, or even the spherical condenser as at present made.

The condensing space in the small metal condenser exhibited, of which the outside dimensions of the body are $\frac{15}{16}$ inch × $4\frac{1}{4}$ inch, is only 9 cubic centimetres. The glass one shown — measuring outside $1\frac{3}{8} \times 5\frac{3}{8}$ inches—has an internal capacity of 30 c.c., while a Liebig's condenser, of which the water-cooled part measured $19 \times \frac{7}{16}$, was found to hold 55 c.c., and a ball condenser $3\frac{1}{2}$ inches in diameter was found to contain over a hundred cubic centimetres.

That the practical performance of the condenser is at least equal to its theoretical promise may be seen from the following figures :—

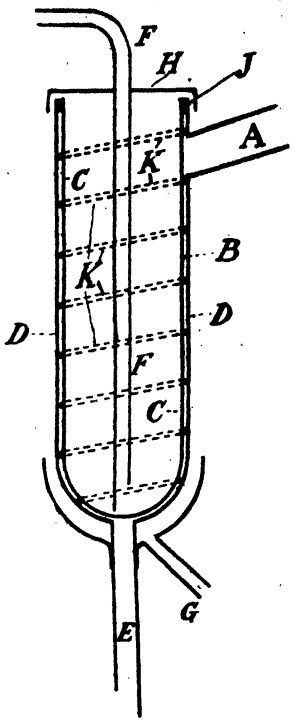

FIG. 2.

	Small Metal Condenser. (1).	(2).	(3).	Glass Condenser. (4).	(5).
Temperature of effluent cooling water ...	52° C.	65° C.	76° C.	61° C.	47·5° C.
Temperature of distillate	48° C.	60° C.	61° C.	41° C.	35·5° C.
C.c. of cooling water used per hour ...	40,000	40,000	7,200	6020	2093
C.c. of distillate per hour	2,642	4,128	1,017	765	355
Ratio of quantity of distillate to that of cooling water	$\frac{1}{15·14}$	$\frac{1}{9·69}$	$\frac{1}{7·8}$	$\frac{1}{7·87}$	$\frac{1}{5·9}$

The resistance of the metal condenser, working as in column (2), was roughly equal to one inch of mercury, the volume of the steam condensed in one second being two hundred times the actual capacity of the condenser. When the water supply was stopped, the resistance rose to $1\frac{3}{4}$ inches of mercury.

One of the metal condensers with a body measuring $4\frac{1}{4} \times 1\frac{7}{8}$ outside, but with an unnecessarily large condensing space, when connected up to a high-pressure boiler

* For all ordinary purposes this is quite unnecessary.

(working at 43 lbs. pressure), yielded 8,040 c.c. of distillate per hour. It was, however, working under somewhat disadvantageous circumstances, as it was found impossible to fix it except in a somewhat slanting position, so that the water ran mainly down one side of the exterior.

The glass condensers have not yet been tested as to their extreme capacity, but they have been found ample for any and all of the ordinary laboratory operations, in which 500 c.c. per hour may be taken as the maximum rate of distillation. The metal forms can be used with a ratio of distillate to cooling water as high as $\frac{1}{3}$ without any steam escaping, though the distillate itself is nearly boiling.

In addition to its great efficiency and extremely small size and weight, the new form of condenser has the following advantages :—

It is always used in one and the same position, *i.e.*, *vertical*, in which it takes up a minimum of bench room, and in which also it is very easily fixed, a little bracket projecting from the wall, or a hole in a block sliding up and down a retort stand being ample for the purpose. If greater rigidity is required, the upper end may also be held by a wire or spring clamp attached to the top of the tube F. It can be made, if necessary, in both metal and glass, so that the inner tube C can be withdrawn from the outer. The whole of the interior of the condensing space is thus at once open to view, and can be wiped dry and clean with a duster.

To effect this in the metal condensers a slip-in or a screw joint is made at J (Fig. 2); in glass condensers the fused joint at J (Fig. 1) is replaced by an india-rubber joint. Owing to the cooling water running down *outside* the condenser, it is practically impossible for the escape tube to get choked up with fur, as happens sometimes to a Liebig's condenser after long-continued use. The escape tube G should be made about twice the diameter of the cold-water delivery tube as a further safeguard.

Owing to the vertical position and to the small diameter of the extremity, the condenser is very easily connected in an air-tight manner to a receiver, so that, with the addition of a little side-tube at L for attachment to a pump, distillation may be conducted under reduced pressures. Or, if a suitable mercury valve be attached to L, and a little air be sucked out at the commencement of the operation, distillation or digestion may be carried on in an entirely closed space.

In tropical climates, or with liquids of exceptionally low boiling-point, the tube C may be filled with ice, and the water allowed to flow up through it.

The very thin layer into which the water is spread when pouring down the outside of the condenser greatly facilitates evaporation, so that the latent heat of vaporization, which has mainly to be derived from the vapour undergoing condensation, effects a great saving in the cooling water used. This is especially the case with liquids boiling above 100° C., but may be easily shown in the case of water by cutting down the supply of cooling water to a minimum, when the water at the top of C is sometimes as much as 10° hotter than that issuing from G.

Finally, its simplicity renders it easy of construction in almost any material likely to be employed.

The condensers can be obtained from Messrs. J. J. Griffin and Sons, Garrick Street, and from Messrs. C. E. Müller and Co., High Holborn.

THE ANALYSIS OF MARMALADE.

By L. K. Boselby, Chemist to Messrs. T. Keiller and Son, Limited.

(*Read at the Meeting, March* 16, 1898.)

Having had occasion lately to work out some methods for the analysis of marmalade and jams, I have thought that a description of these, together with several results showing the composition of marmalade, might be of interest to the members of this Society.

Very few analyses on this subject have been published up to the present time—indeed, a few made by Mr. Carter Bell, the Analyst for Chester, are the only ones I know of. These analyses, which have been published quite recently, are not at all in agreement with any which I have myself made; among them are four analyses of marmalade, of which I give particulars, together with a few quotations from the report: "In the manufacture of jam on a large scale glucose, or inverted sugar, is often used in the place of cane. But to attempt to estimate this adulteration would be hopeless, for in the manufacture of jam the acids of the fruit convert the cane-sugar, more or less, into glucose."

The following analyses are then given:

	Water.	Glucose.	Cane-sugar.	Ash.
1. Marmalade ...	20·5	21·05	37·77	0·305
2. ,, ...	21·8	15·62	34·38	0·31
3. ,, ...	22·5	24·39	25·61	0·30
4. ,, ...	19·5	21·73	14·63	0·26

From the remarks quoted above, it would seem that Mr. Carter Bell is unable to distinguish between the product of the action of sulphuric acid on starch, usually known as glucose, and the product of the action of a fruit acid on cane or beet sugar, usually known as invert sugar.

The sugar estimated in these analyses appears to me to be very much too low; for if the last sample be taken, and the water, glucose, and cane-sugar added together, they amount to 55·86 per cent., a figure which leaves 44·14 per cent. of dry fruit (the water being estimated), which is not possible. My own experience goes to prove that marmalades from various sources contain from 2½ to 5½ per cent. of dried fruit. The probability is that both the figures for water and for sugar are much too low, as I never met with a marmalade with so low a water as 19·5 per cent., and one which contained 36·36 per cent. of total sugar, more than half of which was glucose, would be little thicker than water.

The following are the methods in use in my laboratory:

Water.—This is estimated by taking a flat-bottomed porcelain basin containing a glass rod, and weighing into it about 7 to 8 grammes of the well-mixed marmalade. This is warmed, and dissolved in a few c.c. of 40 per cent. alcohol. From 12 to 15 grammes of silver-sand, which has been previously dried, if necessary, are now weighed into the basin, and the marmalade, sand, and alcohol thoroughly mixed with the glass rod. The basin is then heated on the water-bath for an hour, when 5 c.c. of absolute alcohol are added, and the basin again heated for one hour; after this it is

transferred to the air-bath and dried at 95–100° C. for thirty-six hours, or until the weight is nearly constant.

Acidity.—This is estimated by weighing out 20 grammes of the marmalade, titrating with $\frac{N}{10}$ soda, with phenolphthalein, or litmus-paper as indicator. The number of cubic centimetres used, multiplied by 0·035, gives the percentage calculated as citric acid.

Sugars.—The following methods are the best, supposing only cane and invert sugar to be present: Weigh out 65·12 grammes of the well-mixed marmalade in a small beaker, add successive quantities of *cold* water—say, 50 c.c.—stir well, and decant into a 250 c.c. flask. Then transfer the peel to the flask, add basic lead acetate, until the solution is only slightly acid, make up to 250 c.c., and mix well. It is best not to add sufficient basic lead acetate to neutralize the solution, as one is apt to get lead in the filtrate, this being an objectionable feature, as a slight precipitate is produced on adding acid to invert the solution which is apt to interfere with the polarimeter reading. The contents of the 250 c.c. flask are now filtered through a dry filter, and polarized at $t°$ C. Fifty c.c. of the filtrate are placed in a flask, and 5 c.c. of pure, strong HCl added, and the flask is heated on the water-bath till a thermometer suspended in the middle of the flask indicates 68° C. in ten minutes. Cool quickly to $t°$, and again polarize. Then,

$$\text{Cane-sugar} = \frac{\text{Direct} - \text{inverted reading}}{144 - \frac{t°}{2}} \text{ (this is the well-known Clerget formula).}$$

$$\text{Invert sugar} = \frac{(\text{Cane-sugar} - \text{direct reading})\ 100}{44 - \frac{t°}{2}}.$$

If glucose be present it will be indicated by the inverted reading being + instead of −, or, at all events, being very much smaller than usual. If this be the case, it will be necessary also to determine the cupric reducing power (in duplicate).

The details of the method are as follows: Weigh out 13·024 grammes of pure cane sugar, make up to 100 c.c., add 10 c.c. strong HCl, and invert as before. Cool, take 11 c.c. of this solution, neutralize, and make up to 100 c.c. This I call solution *a*.

Dilute 20 c.c. of the filtrate used for direct polarization, and make up to 100 c.c. This I call solution *b*.

Take two beakers, and in each place 25 c.c. of Soxhlet's copper solution and 25 c.c. of Soxhlet's alkaline tartaric solution and 40 c.c. of water, add to one 10 c.c. of solution *a*, and to the other 10 c.c. of solution *b*. Place both over flames and bring to the boil in four minutes, and boil for four minutes longer, filter off the reduced cuprous oxide, and weigh either as metallic copper or copper oxide. The cupric reducing power of the marmalade, calculated as percentages of invert sugar, will be found by the following formula:

$$= \frac{\text{Cu (or CuO) from } b}{4 \times \text{Cu (or CuO) from } a} \times 100.$$

The reason for making solution *b* four times as strong as solution *a* is that the

cupric reducing power of a marmalade is somewhere in the neighbourhood of 25 per cent.

Calculation of the Percentage of Glucose.—I need hardly point out that "glucose" is not a chemical entity, but is a mixture of maltose, dextrin, dextrose, and probably intermediate compounds. The following table will give the composition of commercial glucoses. The first nine are taken from a paper by Weber and McPhearson ("Proceedings of the Eleventh Annual Convention of the Association of Official Agricultural Chemists," p. 126):

	1.	2.	3.	4.	5.	6.	7.	8.	9.	10.
Total solids	78·9	80·1	80·8	80·3	85·6	87·4	80·0	81·1	86·6	78·9
$[\alpha]_D$ of solids	133·3	132·9	120·6	135·4	132·1	127·8	149·3	130·3	134·9	143·1
Cupric reducing power of solids ...	56·6	57·0	60·6	54·9	56·7	55·9	43·6	50·6	48·8	48·5

Analysis No. 10 is by H. D. Richmond. The average of these ten samples, which may be taken to fairly represent the mean composition of commercial glucose, is: Total solids, 81·9; $[\alpha]_D$ of solids, 133·98; cupric reducing power of solids, 53·31.

From the paper referred to, I find that Weber and MacPhearson found that commercial glucose, on the average, gave, in a solution containing 13·024 grammes per 100 c.c., a

Direct reading	...	...	85·45 sugar degrees.
Inverted reading	...	...	84·9 ,,

The inverted reading is done by the method described above, which must be strictly adhered to, Herzfeld's modification having given a much larger difference. It is seen that the change on inversion is practically nil, and therefore cane-sugar can be estimated in the presence of commercial glucose with very fair accuracy. The average $[\alpha]_D$ of the solids of commercial glucose (133·98) is practically twice that of cane-sugar, and it may be assumed without much error that 1 per cent. of glucose solids will polarize 2 per cent. of cane-sugar. When cane-sugar is inverted, 100 parts become 105·3:

$$C_{12}H_{22}O_{11} + OH_2 = C_6H_{12}O_6 + C_6H_{12}O_6.$$

The cupric reducing power of inverted cane-sugar is therefore 105·3. The cupric reducing power of glucose solids, 53·13, is practically half this, and it may be assumed without much error that 1 per cent. of glucose will have a cupric reducing power equal to 0·5 per cent. of cane-sugar.

To calculate the percentage of cane-sugar, invert sugar, and glucose in a marmalade, the following formulæ can be derived from the facts above mentioned:

$$\text{Cane-sugar} = \frac{\text{Direct} - \text{inverted reading}}{144 - \frac{t^\circ}{2}}.$$

$$\text{Inverted sugar} = \frac{\text{Cane-sugar} - \text{direct reading} + 4 \text{ cupric reducing power}}{4 + 44 - \frac{t^\circ}{2}}$$

$$\text{Glucose} = 2(\text{cupric reducing power} - \text{inverted sugar}).$$

It must be borne in mind that the inverted sugar is given by all the above formulæ as percentages of cane-sugar inverted, and not as percentages of actual invert sugar present. This is done for the sake of convenience, as by adding the cane and inverted sugar together the percentage of cane-sugar present will be given.

As a test analysis, a marmalade, of which the composition was unknown to me, was made up containing:

Cane-sugar	40·0 per cent.
Glucose	20·0 ,,

The figures found on analysis were as follows:

Direct polarization	+61·2 at 16·5 C.
After inversion	+18·2 ,,
Cupric reducing power	16·48

From these results the composition was calculated as follows by the above formulæ:

Cane-sugar ... 31·7 } 40·0 total
Inverted sugar ... 8·3 }
Glucose ... 16·3 = glucose containing 81·9 per cent solids = 19·9 per cent.

This result seems to indicate that cane-sugar, invert sugar, and commercial glucose can be estimated with sufficient accuracy in the presence of each other.

The following analyses give the composition of nearly all the best known brands of marmalade on the market, the results having been all obtained by the methods given above:

	1.	2.	3.	4.	5.
Moisture ...	33·3	33·1	27·7	30·6	31·5
Sugar	37·2	42·1	25·6	32·6	33·2
Inverted sugar ...	25·0	21·0	41·8	32·7	30·0
Acidity	0·5	0·3	0·4	0·4	0·5
Undetermined ...	4·0	3·5	4·5	3·7	4·8
	100·0	100·0	100·0	100·0	100·0

	6.	7.	8.	9.	10.
Water	31·3	26·6	30·0	25·3	31·7
Sugar	34·7	35·6	33·9	22·8	32·8
Inverted sugar ...	23·9	30·4	11·1	38·2	30·4
Glucose ...	8·7	5·0	22·9	11·6	none
Acidity	0·4	0·5	0·4	0·4	0·5

Glucose ...	13·3	14·3	none	none	none
Acidity	0·6	0·4	0·5	0·6	0·5
Undetermined ...	1·6	3·4	6 0	4·2	4·9
	100·0	100·0	100·0	100·0	100·0

	16.
Water	28·6
Sugar	24·3
Inverted sugar	42·8
Acidity	0·6
Undetermined	3·7
	100·0

The sample labelled No. 8 contained added gelatin or isinglass, and the sample No. 16 was one of Messrs. Keiller's marmalade, which had been kept for six years; hence the abnormally high invert sugar. Nos. 11 and 12 were preserved with salicylic acid. The amount of invert sugar formed in a marmalade seems to be due to three causes: Firstly, the amount of acid present; secondly, the length of time the cooking is continued; and, thirdly, the length of time it has been kept. The figures for undetermined matter vary somewhat, but as the error of separating and estimating a complicated mixture of sugars is thrown on this figure it is not surprising.

Sugar is naturally present in oranges, and a correction has been applied for the amount of fruit-sugar present in a marmalade; it consists in subtracting 0·1 sugar degrees from the + reading, and 0·3 from the – reading—that is, supposing the normal quantity of marmalade to have been weighed out, namely, 65·12 grammes per 250 c.c.

In conclusion, I should like to express my thanks to Mr. H. Droop Richmond for help in confirming some of the results given in this paper.

Discussion.

The President having invited discussion,

Mr. A. C. Chapman inquired what assumption Mr. Boseley made in regard to the composition of glucose in the method he had adopted. Ordinary commercial glucose (a mixture of dextrose, maltose, and occasionally dextrin) varied very much in composition. The proportion of maltose, for instance, might be as little as 4 or 5 per cent., or as much as 25 per cent. Some samples contained no dextrin at all, while others contained a fairly considerable quantity. It would be necessary to assume a constant composition as a basis for purposes of analysis and calculation.

Mr. Hehner observed that an important reference had been made in the paper to salicylic acid. Salicylic acid was often found in jam, and had given rise to a good deal of discussion. Mr. Boseley now stated that it was added to jam solely as a means of adulteration, and in view of this he (Mr. Hehner) thought that its presence in jam might be somewhat more vigorously condemned than hitherto. The excuse that it prevented the preserve from going bad, and that it was not particularly harmful, might justify its being passed; but when it was distinctly understood that it also afforded a means of adding water, the matter became very serious.

Mr. L. K. Boseley said, in reply to Mr. Chapman's question, that the basis the calculations had been worked out upon was the cupric reducing power of the glucose, and also the $[\alpha]_D$ of the glucose solids. He was sorry not to have had time enough to make this clear when reading the paper, but Mr. Chapman would understand that the amount of dextrin, dextrose, etc., which the glucose contained did not enter into the calculation, that being based on the average cupric reducing power, etc., of glucose.

NOTE ON THE VOLUME CONCENTRATION OF CONDENSED MILK.

By A. McGill.

The purchaser of condensed milk, as a rule, thinks of its concentration in terms of volume rather than weight; and values a pint of the article more or less highly as he takes it to represent more or less than, say, three pints of the milk used in its preparation. A. H. Allen (see Analyst, xxi., p. 281) has given a formula for calculating, from the results of analysis, the volume concentration of any sample. His formula involves a knowledge of the specific gravity of the sample, and assumes the normal character of the milk from which the condensed article is made.

I would suggest the *solids-not-fat* instead of the *total solids* as a basis for calculation of the concentration. It is mainly in the partial or entire removal of the fat before manufacture that condensed milks differ from each other; and although, in the case of a whole milk, it makes little difference whether total solids or solids-not-fat is employed in the calculation, the error is very considerable when a skimmed milk is in question.

The following examples, taken from the analyses of Pearmain and Moor (Analyst, xx., 272), illustrate this:

Brand.	Concentration based on Total Solids = 12·5 per cent.	Concentration based on Solids-not-Fat = 8·5 per cent.
Milkmaid	... 3·85 ...	... 4·02
Lancer	... 3·26 ...	... 4·74

These figures are calculated by Mr. Allen's formula, in which the density of normal milk is taken as 1, and that of condensed milk as 1·28. My own experience shows that most samples of sweetened condensed milk have a gravity of 1·31 to 1·33; and I prefer to use the number 1·03, instead of unity, as the average density of normal milk. The density of condensed milk is not easily taken upon the sample itself. I prepare a solution of 50 grammes to 250 c.c., and from the density of this solution calculate that of the original sample by the formula:

$$\text{Original density} = \frac{1}{6 - 5a}, \quad \text{when } (a) = \text{density of the dilute milk.}$$

If these changes be made, the numbers already given for Milkmaid and Lancer brands will become 4·01 and 4·75, instead of 4·02 and 4·74; so that, for practical purposes, it is of little consequence which pair of numbers is used. If, however, the true density of the sample be used in calculation, while the density of normal milk is taken as unity, the numbers become 4·13 and 4·84 respectively.

The formulæ used may be written as follows:

Let n = solids-not-fat in normal milk.
" n_1 = solids-not-fat in samples.
" d = density normal milk.
" d_1 = density of sample.
" f = fat in milk used in manufacture.
" f_1 = fat found in sample.
" c = volume concentration.

$$\text{Then, } c = \frac{n_1 \times d_1}{n \times d} = \frac{n_1 \times d_1}{8{\cdot}5 \times 1{\cdot}03} = \frac{n_1 \times d_1}{8{\cdot}755}.$$

$$f = \frac{n \times f_1}{n_1} = \frac{8{\cdot}5\, f_1}{n_1}.$$

Thus, the fat percentage in the original milk used in preparing the Milkmaid brand is found to be 3·515.

LABORATORY OF THE INLAND REVENUE DEPARTMENT, OTTAWA,
January 15, 1898.

THE INSTITUTE OF CHEMISTRY.

THE annual dinne of the Fellows and Associates of the Institute of Chemistry took place last night at the Trocadero Restaurant, Piccadilly Circus. The president, Dr. T. Stevenson (official analyst to the Home Office), occupied the chair, and the large company present included Lord Reay, Mr. Justice Byrne, Sir J. Evans (treasurer Royal Society), Sir E. Frankland, Sir H. T. Wood (secretary of the Society of Arts), Mr. K. E. Digby, Dr. Bernard Dyer, Dr. W. J. Russell, Dr. Thorpe, Mr. T. H. Elliott, Mr. J. F. Moulton, Q.C., Mr. H. Kearley, M.P., Mr. H. H. Cozens-Hardy, M.P., Professor Dewar, Dr. J. H. Gladstone, Dr. Ludwig Mond, Mr. W. Hills (president of the Pharmaceutical Society), Dr. H. E. Armstrong, Dr. W. J. Sykes, Dr. J. A. Voelcker, Mr. Otto Hehner, Professor J. M. Thomson, Mr. D. Howard, Mr. R. J. Friswell, Mr. T. Fairley, Dr. Corfield, Dr. Wynter Blyth, and Mr. R. B. Pilcher (secretary). Mr. Justice Byrne proposed "The Institute of Chemistry," and the President, in responding, mentioned that the register of the society now contained the names of 826 Fellows and 120 Associates, while there were over 180 registered students training for the examination at the various colleges recognised by the Institute. He looked forward to the time when professional chemists would be endowed with the power of conferring diplomas, and exercising the same restrictive functions as were already possessed by the professions of the law and physic. Other toasts followed. (Abridged from the *Times*.)

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Black Pepper from Mangalore. T. F. Hanansek. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 153.)—Among a collection of samples of pepper supplied by Messrs. Lewis and Peat, of London, was a variety of black pepper from Mangalore, which differs considerably from the sorts usually met with. The author is not aware if it is on the English market to any large extent, but in Germany and Austria it is quite unknown. Its place of origin, Mangalore, is a town on the west coast of India, between Goa and Cochin, and therefore in the heart of the pepper-growing district. The pepper-corns are about 7 mm. in diameter, of a deep black colour, and either nearly spherical or somewhat egg-shaped. One hundred of the

peppercorns weigh 8·6 grammes. They possess a very powerful pepper taste and odour. The ash amounts to 3·43 per cent. The microscopic examination of the husk reveals much the same general structure as the husk of ordinary pepper. Illustrations are given showing the microscopic appearance of sections of the peppercorns, the cells, etc. H. H. B. S.

Glucose in Butter. C. A. Crampton. (*Jour. Amer. Chem. Soc.*, 1898, xx., 201-206.)—The author states that the method found most satisfactory by the manufacturers for preserving butter for export to tropical countries is by the addition of considerable quantities of salt and of glucose. The following table gives the results of the analyses of three samples of such prepared butter:

	No. 2,434. Butter exported from the United States to Brazil.	No. 2,443. Butter exported to Brazil and returned to U.S.A.	No. 2,460. *Beurre Rouge* exported to Guadeloupe.
Water	16·29	18·93	21·60
Casein (N × 6·25) ...	1·19	1·06	0·81
Ash	7·00	6·19	16·42
Fat	72·16	69·67	51 15
Glucose (by difference) ...	3·36	4·15	10·02
	100·00	100·00	100·00

The characteristics of the fat separated from these three butters were not abnormal, though the Reichert-Meissl value of No. 2,443 was somewhat low (25·4). For this reason the Brazilian authorities rejected the butter, but the glucose escaped their notice. This butter when returned was still passable.

A sample of the glucose used for this purpose was found by the author to consist of the ordinary syrup known as confectioner's glucose. It contained 16·5 per cent. of water, and gave $[\alpha]_D = 119·3$.

As to its detection in butter, it is shown that on extracting the fat with ether, and determining the casein by loss on ignition, the results are abnormally high and widely different to those obtained by calculating the casein from the amount of nitrogen; whereas with pure butter the figures are in close agreement.

For a direct determination of the glucose, 10 grammes of the butter are treated with successive portions of hot water in a separatory funnel, and the resulting solution made up to 250 c.c. A slight reduction of Fehling's solution by this solution might be due to milk-sugar or some of the albuminoid substances, but any considerable reduction must be attributed to the presence of sugar or glucose. The optical rotation can be determined in the same solution previously clarified by means of alumina cream or acid mercuric nitrate solution.

The figures given by the author show that either method gives reliable results.

ORGANIC ANALYSIS.

A Colour Reaction of Ethylic Aldehyde. L. Simon. (*Comptes rendus*, vol. cxxv., p. 1105; through *Rev. Chim. Analyt. appl.*, vol. vi. [5], p. 79.)—By adding to a dilute aqueous solution of ethylic aldehyde a few drops of trimethylamine followed by several drops of an almost colorless solution of sodium nitro-prusside, there gradually develops a beautiful blue coloration, which is intense in the case of a 1 per 1,000 solution, and apparent down to a degree of dilution equal to $\frac{1}{25000}$. No other aldehyde or ketone substance gives this reaction, neither does pure ether, although the coloration appears when the latter contains $\frac{1}{2000}$ of aldehyde. Ammonia cannot replace trimethylamine, since it prevents the appearance of the coloration, and destroys it if already formed. C. S.

Colour Reaction of Phenylhydrazine. L. Simon. (*Comptes rendus*, vol. cxxvi., p. 483; through *Rev. Chim. Analyt. appl.*, vol. vi. [6], pp. 79, 80.)—When phenylhydrazine solution is heated for a few moments with a few drops of an aqueous solution of trimethylamine followed by a few drops of sodium nitro-prusside, and by concentrated potash, a bright blue coloration is produced, which is greenish in presence of an excess of nitro-prusside, and deepens on adding the potash, and is converted into sky-blue if acetic acid be added as well. The coloration, which enables $\frac{1}{50000}$ part of phenylhydrazine to be detected, is distinguishable from that produced by ethyl aldehyde (see preceding abstract) by its persistence in presence of potash, ammonia, and acetic acid; it is, however, fugitive, and disappears in about a quarter of an hour. Whilst alcohol, ether and ammonia do not prevent the reaction, chloroform and benzene retard it, as do also mineral and organic acids previous to the addition of potash. It appears to be exclusively characteristic for phenylhydrazine and the derivatives of the latter substituted in the aromatic nucleus. C. S.

Characteristic Colour Reaction of Cotton-seed-Oil. G. Halphen. (*Ann. Chim. Analyt.*, vol. iii. [1], pp. 9-11.)—The development of the red coloration produced by cotton seed-oil in presence of carbon disulphide can be accelerated, so as to be utilizable for the purposes of qualitative analysis, by the presence of free sulphur in the solvent, and the addition of amyl alcohol.

Equal volumes (1 to 3 c.c.) of the oil under examination, amyl alcohol, and carbon disulphide containing 1 per cent. of dissolved sulphur, are placed in a test-tube, which is then partly immersed in a boiling brine-bath for ten to fifteen minutes. A red or orange coloration denotes the presence of cotton-seed-oil. If, however, no change is observed, another 1 c.c. of the same carbon disulphide is added, and heat again applied for five to ten minutes, this operation being repeated in the event of the result again proving negative. As little as 5 per cent. of cotton-seed-oil can be readily detected in this manner. C. S.

Analysis of Fats. Melting-points of Cholesterin and Phytosterin. A. Bömer. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 81.)—The melting-point of cholesterin from animal sources (excluding butter) fluctuates, according to most observers, between 144·5° and 146° C., and of phytosterin from vegetable sources between 131·5° and 138° C. The author has made a large number of determinations of the melting-points of cholesterin and phytosterin extracted from different animal and vegetable sources by the method recently published by him (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 21-49; ANALYST, xxiii., 42), and in order to arrive at as exact results as possible, he in every case repeatedly recrystallized the products, determining the melting-points after each crystallization, until constant. The determinations of the melting-points of thirty-eight specimens of cholesterin from various kinds of pig-fat gave results as follows:

	First Indications of Melting.	First Indications of Flowing.
Minimum	146·0°	146·5°
Maximum	148·0°	148·3°
Mean	146·7°	147·4°

According to Salkowski, the melting-point of cholesterin from butter is abnormal. He found that, even after repeated crystallization, the product, though apparently quite pure and white, melted persistently at about 5° below the ordinary melting-point of cholesterin, a peculiarity which he explained by supposing that it contained a proportion of phytosterin. The author's experiments, however, show that, if carefully purified, butter cholesterin melts quite normally at 146° and over. Crude cholesterin prepared from butter is by no means so pure as that prepared from lard. It contains two impurities in considerable proportions—viz., coloring matter and lecithin, and while the latter is very difficult to separate, its presence has a marked effect in reducing the melting-point of the product. The author further observes that if phytosterin were present in conjunction with cholesterin, its presence would certainly be revealed by the appearance of the crystals.

The determinations of the melting-points of specimens of phytosterin prepared from various vegetable fats gave results as follows:

	First Indications of Melting.	First Indications of Flowing.
Minimum	135·5°	136·0°
Maximum	141·0°	141·5°
Mean	137·5°	137·8°

Experiments upon the melting-points of mixtures of cholesterin and phytosterin showed that the melting-point of a mixture approximates to that obtained by calculation from the melting-points of its components, though a mixture of 3 parts of phytosterin and 1 of cholesterin gives a slightly lower, and a mixture in the reverse proportions a slightly higher, melting-point than the calculated. Mixtures of cholesterin and phytosterin cannot be separated into their components by crystallization.

The determination of cholesterin may be found useful for the following purposes:

1. The detection of vegetable oils in cod-liver-oil.
2. The detection of cotton-seed-oil in lard, etc.

3. The detection of margarine in butter, in cases where the Reichert-Meissl method fails. Margarine being rarely free from vegetable oils, the determination of phytosterin affords a valuable means for its detection. H. H. B. S.

Technical Analysis of Bone-fat. A. A. Shukoff and P. J. Schestakoff. (*Chem. Rev. Fett u. Harz-Ind.*, vol. v. [1], pp. 5-8; [2], pp. 21-23.)—1. *Estimation of Water.*—The ordinary method of determination, by drying 5 grammes of fat at 100° to 110° C. in the oven until of constant weight, is adopted. The time occupied depends on the purity of the fat; bone fats containing lime salts often require over twenty-four hours owing to the tenacity with which these impurities retain moisture.

The Tate method of heating at 130° C. until the evolution of gas ceases gives results below the truth. When lime salts are present, the use of a current of carbon dioxide for accelerating drying is not feasible, owing to the frothing produced.

2. *Extraneous Admixtures.*—These comprise (organic) dirt, sand, calcium phosphate, and lime soaps. In the ordinary method of estimation by dissolving the fat in petroleum spirit or carbon disulphide, considerable differences exist in the amount of insoluble residue, the influential factors being the solvent, the temperature, the duration of the operation, and the presence or absence of water. Carbon disulphide dissolves more of the lime salts than does petroleum spirit, and in most cases reprecipitation occurs on standing or cooling. Undried fat leaves a much larger proportion of lime salts as insoluble residue than dried fat.

Apart from the question whether, in view of their high percentage of fatty acid, lime soaps can properly be regarded as impurities (though their presence is inconvenient when the fat is to be converted into soap), the solution method does not give accurate results, and other means must be employed (see §§ 3 and 4).

3. *Ash.*—This must be determined by combustion of the entire fat, and not merely from the residue left by solvents. The principal constituent being calcium carbonate and oxide, the amount of calcium can be determined by titration, and the amount of lime soaps by calculation from the result, 260 being taken as the average molecular weight of the fatty acids. When sand, calcium phosphate, etc., are present, a quantitative analysis of the ash must be made, but this is seldom necessary.

4. *Direct Estimation of the Pure Fat.*—In place of the usual, but erroneous, method of determining this chief constituent by difference, the authors propose the following:

About 10 grammes of fat are gently heated, with frequent shaking, for about an hour on the water-bath, with 3 to 5 drops of strong hydrochloric acid to decompose the lime soaps, and are then dissolved in 40 c.c. of light petroleum spirit. The solution is decanted from the acid through a tared filter, and is then distilled along with the (two or three) washings to drive off the bulk of the solvent, the pure fat thus obtained being finally dried at 100° to 110° C., with the acid of a current of carbon dioxide, until constant.

The residual acid and dirt are rinsed with water through the same filter, and the impurities determined therefrom.

Water can be estimated by difference to check the results obtained by direct determination.

5. *Unsaponifiable Matter.*—The results furnished by the Allen and Thomson method are higher than by that of Morawski and Demsky, owing to the more complete extraction of the cholesterin. The former method, however, is inaccurate owing to the solution of a portion of the soap in the ether employed, and the authors therefore recommend the following modification :

Five grammes of fat and 25 c.c. of 8 per cent. alcoholic caustic soda are evaporated to dryness, taken up with 80 c.c. of water and extracted with an equal volume of ordinary ether in a separating funnel, the separation of the liquids being facilitated, if necessary, by the addition of alcohol, but avoiding an excess of the latter. After the third extraction the ethereal solution is evaporated without washing, the residue is rendered alkaline by normal caustic soda and re-dissolved in petroleum spirit, which solution yields on filtration and evaporation an ashless residue.

The technical importance of the unsaponifiable residue depends on the use to which the fat is put; for soap-making it must be looked on as an impurity and deducted from the total fat, whilst for the stearin industry the presence of cholesterin is no drawback.

The solidifying-point of the fatty acids is determined by the original Dalican method. C. S.

Precipitation of the Albumoses by Zinc Sulphate. K. Baumann and A. Bömer. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 106.)—In a former paper by one of the authors (A. Bömer, *Zeit. anal. Chemie.*, 1895, 562) zinc sulphate was proposed in place of ammonium sulphate as a precipitant for the albumoses The authors have further investigated the subject, and arrived at the following results :

1. If 1 c.c. of dilute sulphuric acid (1 : 4) be added to 50 c.c. of solution, the albumoses are precipitated as well with zinc sulphate as with ammonium sulphate.

2. Ammonium salts, tyrosine and kreatine are not precipitated by zinc sulphate. Leucine is thrown down in small quantities, but considering the small amount present in meat preparations the error is not material. Leucine and tyrosine are, on the other hand, both separated in considerable quantities by ammonium sulphate.

3. The meat bases are as completely separated by phosphomolybdic acid in the filtrate from the zinc sulphate precipitation as they are in an aqueous solution, and the peptones are even more completely separated.

4. The filtrate from the precipitation of the albumoses can be precipitated directly with phosphomolybdic acid, thus avoiding the error caused by the different nitrogen contents of the albumin and gelatin albumoses.

5. Ammonia and kreatine are separated from solutions by sodium phosphomolybdate with almost quantitative exactness.

The authors propose the following method for the determination of the albumoses and peptones in meat extracts and peptone preparations : Fifty c.c. of solution

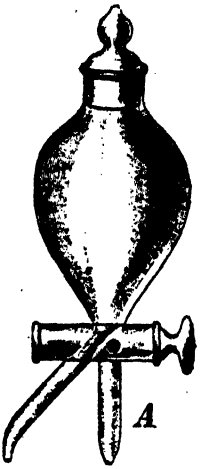
containing about 1 gramme of dry substance are freed from insoluble and coagulable albumin, and mixed with 1 c.c. of dilute sulphuric acid (1 : 4) and sufficient zinc sulphate added to supersaturation. The precipitate is filtered off and washed with a slightly acidified saturated solution of zinc sulphate, and the nitrogen determined by Kjeldahl's method. In the filtrate the peptones, meat bases, and ammonia are precipitated by sodium phosphomolybdate. The precipitate is filtered off, and the nitrogen also of this determined by Kjeldahl's method. The ammoniacal nitrogen is determined, either in the aqueous solution, or, better still, in a second phosphomolybdate precipitate by distillation with magnesia. The amount so found being deducted from the total nitrogen in the phosphomolybdate precipitate gives by difference the nitrogen present as peptones and meat bases with, under certain circumstances, small quantities of leucine. H. H. B. S.

INORGANIC ANALYSIS.

Volumetric Determination of Antimony. H. Causse. (*Comptes rendus*, vol. cxxv., p. 1100; through *Rev. Chim. Analyt. appl.*, vol. vi. [3], p. 31.)—The method is based on the conversion of antimonious acid into antimonic acid by iodic acid. As reagents the author employs: (1) Iodic acid solution, containing 200 grammes per litre, prepared beforehand in order to allow the barium iodate, almost always present in the commercial acid, to subside. (2) Decinormal sodium thiosulphate solution. (3) A 20 per cent. solution of potassium iodide. (4) Fresh starch paste.

Antimony oxide (0·50 to 0·60 gramme) is placed in the apparatus used by Mohr or Fresenius in estimating iodine, and 20 to 25 c.c. of iodic acid are added, 10 c.c. of potassium iodide being placed in the tube condenser. On heating gradually to boiling, the iodine is liberated, absorbed by the iodide solution, and the iodine determined by titration with sodium thiosulphate. C. S.

Estimation of Metallic Iron in Iron reduced by Hydrogen. Dr. Schmidt. (*Vers. deutsch. Naturf. u. Aertze;* through *Rev. Chim. Analyt. appl.*, vol. vi. [3], p. 32.)—0·4 gramme of reduced iron is attacked in a 100 c.c. flask by 2 to 2·5 grammes of iodine (accurately weighed) in presence of 5 to 10 c.c. of water; the iron alone is dissolved under these conditions, leaving the oxide. One gramme of potassium iodide is then added and the liquid made up to 100 c.c., the excess of iodine being titrated with sodium thiosulphate. C. S.



Contribution to our Knowledge of the Rare Earths. L. Haber. (*Monatsheft für Chemie*, xviii., 687.)—The author has studied the behaviour of the rare earths to chromic acid, potassium bichromate, sodium acetate and formate, and to tartaric, citric, and malic acids. The various reactions are summarized in the following table:

	Chromic Acid.	Potassium or Sodium Bichromate.	Sodium Acetate.	Sodium Formate.	Tartaric Acid.	Citric Acid.	Malic Acid.
Thorium -	Precipitates on boiling with difficulty and incompletely. Precipitate is orange-yellow and distinctly crystalline.	Precipitates easily from sufficiently diluted solutions on boiling. Precipitation is incomplete, and precipitate insoluble in water.	Precipitates from not too dilute solutions on boiling. Precipitate is white and crystalline.	Precipitates with difficulty on boiling. Precipitate is white and crystalline.	Precipitates easily, but incompletely, on boiling. Precipitate is white and flocky, and soluble in sodium acetate and formate.	Precipitates easily, like the preceding. Soluble in sodium acetate and formate.	Precipitates on boiling as a white, crystalline precipitate; soluble in sodium acetate and formate.
Zirconium	Precipitates moderately, easily, and completely on boiling. Precipitate orange-yellow and flocky.	Precipitates in a flocky condition, very easily on boiling.	Precipitates very easily and completely on boiling. Precipitate is white and flocky.	Precipitates very easily on boiling. Precipitate is white and flocky.	Precipitates incompletely in a fine flocky condition; soluble in sodium acetate and in excess of precipitant.	Precipitates easily in a flocky condition on boiling. Soluble in sodium acetate and in excess of precipitant.	Precipitates easily on boiling. Flocky; soluble in sodium acetate and in excess of precipitant.
Cerium -	Not precipitated.	Not precipitated.	Not precipitated.	Precipitates incompletely from concentrated solutions. Precipitate is beautifully crystalline.	Not precipitated.	Not precipitated.	Not precipitated.
Lanthanum	Not precipitated.	Not precipitated.	Not precipitated.	Precipitates incompletely from concentrated solutions. Beautifully crystalline.	Not precipitated.	Not precipitated.	Not precipitated.
Didymium	Not precipitated.	Not precipitated.	Not precipitated.	Precipitates incompletely from concentrated solutions. Beautifully crystalline.	Not precipitated.	Not precipitated.	Not precipitated.
Yttria - -	Not precipitated.	Not precipitated.	Precipitates with difficulty from concentrated solutions.	(?)	(?)	(?)	(?)

Thorium and zirconium are both characterized by the formation of basic salts with the organic acids; but whereas the thorium salts appear to be of constant composition, the zirconium compounds by continued treatment with water undergo a gradual change towards the condition of hydrate. H. H. B. S.

APPARATUS.

A New Separating Funnel. E. Spaeth. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1896, 96.)—The funnel is provided with a two-way stopcock, the channels of which are separate and distinct from each other. One channel is straight and the other oblique, and each connects with a separate efflux tubulure, as shown in Fig. A. It is also provided with a stand, shown in Fig. B. In using the funnel it is obvious that, after the lower layer of liquid has been drawn off through the vertical channel, the upper layer can be run out through the other, which will be quite clean and uncontaminated. H. H. B. S.

MISCELLANEOUS.

The following article appeared in the *Times* of April 18, 1898:

"POLLUTED WATER AND SOMERSET HOUSE.

"(FROM A CORRESPONDENT.)

"After the experiences of Maidstone last winter, it might be expected that at least no obstacles would be placed in the way of the sanitary authority in dealing with all possible sources of danger within their jurisdiction. The public will, therefore, learn with astonishment that their efforts to do their duty by the community and to prevent the continued use of water from a dangerous source have been frustrated by the action of the local justices, with the assistance of two Government officials attached to the Inland Revenue Department. The whole case is so irregular, and so important to all sanitary authorities, that it deserves the widest publicity. The facts are briefly these:

"In Maidstone, as in most other towns, there are, in addition to the public water supply, a certain number of wells still in use. One of these, situated in Orchard Street, supplies four houses in that street which have not had the public water laid on. In the immediate neighbourhood fourteen cases of typhoid fever occurred in ten houses, distributed on all sides of the spot where the well is, and in dangerous proximity to it. The water, on being analysed by the

medical officer of health—who is also analyst to the county of Kent, and an exceptionally competent authority—showed signs of organic impurity, not to an alarming extent when taken by themselves, but more than sufficient to prove danger when taken in conjunction with the situation of the well and the known defective condition of the house-drains near it. The medical officer, guided by all the circumstances, condemned the water for drinking purposes, as every competent officer must have done in his position; but he did not recommend compulsory closure of the well, hoping to attain the same end more easily by persuasion. The wording of the Act makes it very difficult to obtain an order for compulsory closing except on chemical grounds, and in this case the chemical evidence was of less weight than the other conditions, and, apart from them, susceptible of a more favourable interpretation. However, the sanitary authority, actuated by a laudable anxiety to protect the town, applied for a closing order. It should be observed here that there is no reason why the well should not be closed, as the public water-supply is laid on in the street. The case came on for the first time on January 25, when it was adjourned for the defendant's chemist to attend. At the second hearing, on February 15, two chemists appeared for the defendant, and pronounced the water wholesome on chemical grounds, as they were quite entitled to do. The results of their analysis agreed with those of the medical officer; the difference lay in his interpretation, which was influenced by knowledge not within the reach of the other chemists. The magistrates then took a most singular step. They adjourned a second time, and ordered a sample to be sent to the Inland Revenue Department at Somerset House. At the third hearing, on March 15, a certificate was produced, signed by two officials in the Government laboratory, but not by the principal. The certificate, after giving the results of the analysis, which agreed in the main with those previously made, went on to say: 'From a consideration of all the results of the analyses there are grounds for stating that the water is not liable to contamination from the immediate neighbourhood of the well, and, although the water on account of its hardness could not be recommended for general domestic purposes, we are of opinion that its use for potable purposes is not likely to prove injurious or dangerous to health.' The magistrates thereupon dismissed the application, with costs against the sanitary authority. The public importance of the case lies in the fact that wells of this kind are one of the most dangerous and troublesome sources of disease with which sanitary authorities have to deal. It is difficult enough to get them closed at any time under the law, but if the analysts of Somerset House are to be made the arbiters—which is not provided by the law—it will clearly become impossible. Though doubtless highly competent in their own line, they have nothing to do with water, and still less to do with sanitation. By the Food and Drugs Act of 1875 the Inland Revenue Laboratory was appointed referee for the analysis of food and drugs in disputed cases, but water is expressly exempted by section 2 of the Act. Somerset House therefore, has no official or legal *status* in the present case. The terms of the certificate quoted above are a sufficient proof that it ought not to be allowed to usurp any such *status*. An analyst has a perfect right to say that a sample of water submitted to him is wholesome and fit to drink, but no one possessing an elementary knowledge of sanitary science would venture to certify, on chemical grounds, that a water is 'not liable to contamination,' or 'not likely to prove dangerous to health.' Those are questions the answer to which depends on the conditions surrounding the source of the water. A perfectly pure water may obviously be liable to dangerous pollution if the circumstances favour it. The greatest authorities have long ago laid down the axiom, which is now universally accepted, that chemical analysis can only be accepted as positive evidence of danger, not as negative evidence as to its absence. To use the words of the late Sir George Buchanan: 'The chemist can tell us of impurity and hazard, but not of purity and safety. For information about these we must go, with the aid of what the chemist has been able to teach us, in search of the conditions surrounding the water sources.' The same principle has been further laid down by the Local Government Board in relation to wells precisely similar to the one in question—'We must go beyond the laboratory for evidence of any drinking water being free from dangerous organic pollution.' When a water actually shows traces of organic impurity, it is an astonishing subversion of established principles for any responsible person to give a certificate of safety, not only in the present but for the future, on the strength of analysis alone and without taking the surrounding conditions into account. Considering what they are in the case of the Orchard Street well, one can only describe such a certificate as reckless. The danger to be apprehended is that specific pollution, which there is reason to believe has soaked into the ground, will gradually find its way into the well. The results of the three analyses confirm that danger. There is no discrepancy between them, but the two later ones indicate somewhat more impurity than that originally made, and point to a process of progressive pollution. The medical officer has recommended his committee to apply for the intervention of the Local Government Board, which is the proper authority to decide

the case; and meanwhile the action of the Somerset House analysts is to be brought up in the House of Commons immediately. The interference with the sanitary administration of the country by a Government department which possesses neither authority nor knowledge of the subject is wholly mischievous. In Maidstone alone there are several other wells which ought to be closed, but in face of recent proceedings it is obviously useless for the sanitary authority to take action."

[The following table, extracted from a report by Mr. Matthew A. Adams, F.R.C.S., F.I.C., of the case referred to, shows the local standard for unpolluted ragstone water, the results of the analysis of the water from the well condemned by Mr. Adams, the results of the analysis made by Mr. Gregory on behalf of the owner of the well, and the results of the analysis made by the chemists of the Inland Revenue Department. A full copy of the report made by the Government chemists is also appended.]

WATER ANALYSIS—REPORT.

	Local Standard for Ragstone Water Conduit Supply.	Adams. Sept. 17, 1897.	Gregory. Dec. 2, 1897.	Somerset House. Feb. 16, 1898.
Total solids	32·89	53·6	52·0	54·1
Loss on ignition	2·51	2·0	?	?
Chlorine	2·30	3·4	3·01	2·7
Nitrogen as nitrates ...	·466	1·14	1·840	1·81
Free ammonia	·005	·00	·02	·01
Albuminoid ammonia ...	·015	·05	·03	·064
Oxygen absorbed in ¼ hour	·008	·013	·0096	·0063
„ „ in 4 hours	·018	·018		
Hardness, total	17·4	23·1	33·6	34·0
„ permanent ...	6·5	15·6		20·0
Appearance in 2-foot tube ...	Clear p. blue	Greenish blue, rather dirty.		Clear, colourless
Smell	None	None		None
Phosphoric acid	Trace	Slight trace.		Trace
Nitrites				Trace

All results are given in grains per gallon, except free and albuminoid ammonia, which are in parts per million.

GOVERNMENT LABORATORY,
SOMERSET HOUSE, LONDON, W.C.

The sample of water referred to in your letter of the 16th ultimo, and stated on label to have been obtained from "Orchard Street," on "16th of February, 1898," was received here on the following day, securely sealed. The water was found to be colourless, clear, and odourless.

We hereby certify that we have analysed the water, and declare the results of our analysis to be as follows:

Albuminoid ammonia ... ... =	·0064	Parts per 100,000.
Free ammonia ... ... =	·001	
Oxygen consumed ... ... =	·009	
Total solids (dried at 212° F.) ... ... =	54·1	Grains per gallon.
Chlorides (stated as sodium chloride) ... ... =	4·45	
Nitrates (stated as nitrogen) ... ... =	1·81	
Nitrites ... ... =	trace.	
Total hardness ... ... =	34·0	Degrees per Gallon.
Permanent hardness ... ... =	20·0	

Judging from the figures shown under the terms "albuminoid ammonia" and "oxygen consumed," the water is regarded as of fair quality, and the results in these respects compare favourably with those obtained from samples of water drawn from the mains of the London Water Companies during the month of December. The proportion of nitrates is rather high, but having regard to the character of the mineral constituents of the sample, it does not indicate that the water is exposed to organic contamination.

The amount of chlorides for so hard a water is not regarded as excessive.

From a consideration of all the results of the analysis, there are grounds for stating that the water is not liable to contamination from the immediate neighbourhood of the well; and although the water, on account of its hardness, could not be recommended for general domestic purposes, we are of opinion that its use for potable purposes is not likely to prove injurious or dangerous to health.

As witness our hands this Eleventh day of March, 1898.

The Clerk to the Magistrates, Maidstone. (Signed) R. BANNISTER, G. LEWIN.

[On Thursday, April 21, a question was put in the House of Commons to the Secretary to the Treasury on the case referred to. The following is a report of the proceedings.]

HOUSE OF COMMONS,
Thursday, April 21, 1898.

Mr. HENRY J. WILSON asked the Secretary to the Treasury, in view of the fact that the chemical officers of the Inland Revenue are appointed referees in disputed cases of adulteration under the Sale of Food and Drugs Act, and that water is specially excluded from the operation of that Act under Clause 3, would he state whether it was in any way the duty of the chemical officers to undertake the analysis of water for sanitary purposes, and act as referees in disputed cases; and under what authority the chemical officers of the Inland Revenue recently analysed the water taken from a well at Maidstone, known as Prosser's Well, and in their report expressed the opinion that the water was not liable to contamination?

Whether, as a consequence of such report, the application to the Court to close the well was refused?

Was he aware that this well is in close proximity to houses in which no less than fourteen cases of enteric fever occurred during the recent epidemic?

And whether, seeing that the report was not signed by the chief of the laboratory, the action of these chemical officers was sanctioned by the responsible authority?

Mr. HANBURY: Under section 70 of the Public Health Act, 38 and 39 Vict., cap. 55, the magistrates are empowered, if they see fit, to cause water of which complaint is made to be analysed at the cost of the local authority. In cases of difficulty magistrates occasionally ask for the assistance of the Government laboratory, and it has been the practice for many years, when such assistance is asked for by the Court, to undertake an analysis of the water. In the present instance, the justices at Maidstone requested the assistance of the Government laboratory, and it was given in accordance with the usual practice. With regard to the latter part of the question, I understand that evidence as to the possibility of danger arising from the local surroundings of the well was given before the Court by the Medical Officer of Health, and that the magistrates, on consideration of all the evidence before them, decided to refuse the application. The action of the laboratory officers was not specially sanctioned by the Board of Inland Revenue in the particular instance. But these officers undertook the analysis at the request of the magistrates, in accordance with a practice which has for years existed with the approval of the Board.

Mr. JOHN ELLIS: Is the right hon. gentleman aware that the report which the officers drew up went far in excess of anything with which they were justified in dealing?

Mr. HANBURY: I think their report would go perhaps beyond their powers (hear, hear).

[The *Times* of April 19 draws attention to a somewhat similar case, reported in the ANALYST for October, 1893.]

THE ANALYST.

JUNE, 1898.

THE LATE LORD PLAYFAIR, G.C.B., LL.D., F.R.S.

We regret to announce the death, in his seventy-ninth year, of the Right Hon. Lord Playfair. Before he abandoned science for politics, Lord Playfair had a close connection with chemistry, which in his early youth he studied at the University of St. Andrews and at the Andersonian Institution, Glasgow, as well as under Graham at University College. He subsequently went to Giessen, where he became a pupil of Liebig, whom personally, as well as through his translations of the works of the great German chemist, he was instrumental in introducing to the British public. For some years he was engaged in industrial chemistry, and in 1843 was appointed Professor of Chemistry at the Royal Institution at Manchester, a post which he retained until, in 1846, in recognition of his services on a Royal Sanitary Commission, he obtained a Government appointment, as chemist to the Museum of Practical Geology. After a good deal of official work in connection with the 1851 exhibition, he was appointed Professor of Chemistry at the University of Edinburgh, a post which he held for thirteen years, during which time he took an official part in various public duties. Towards the close of this period he entered Parliament, and has ever since been chiefly known in connection with social, parliamentary, and political work, lying outside of the more strictly scientific pursuits of his earlier life. He was made K.C.B. in 1883, and created a peer in 1892. He was a founder of the Chemical Society, whose presidential chair he occupied many years ago.

Lord Playfair was elected an honorary member of the Society of Public Analysts in 1875, in recognition of the strenuous and successful exertions which he had made in the House of Commons for the improvement of the Sale of Food and Drugs Bill, which passed into law in that year, a similar compliment being at the same time paid to his then colleague in the House of Commons, Dr. (now Sir Charles) Cameron.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

The monthly meeting of the society was held on Wednesday evening, May 4, in the Chemical Society's Rooms, Burlington House, Piccadilly, the President (Dr. Bernard Dyer) being in the chair.

The minutes of the previous meeting were read and confirmed.

Mr. H. J. Lewin, analyst at the Royal Victoria Yard, Deptford, was proposed for

election as a member of the society; and Mr. F. M. Wharton, A.I.C., assistant to Mr. Chattaway, was proposed for election as an associate.

A paper was read by Dr. Matthew A. Adams, F.R.C.S., F.I.C., on "Water Supply in Relation to the Maidstone Epidemic."

WATER-SUPPLY IN RELATION TO THE MAIDSTONE EPIDEMIC.

By M. A. Adams, F.R.C.S., F.I.C.

(*Read at the Meeting, May* 4, 1898.)

The observations and experiments I have the pleasure of bringing under your notice to-night, however commonplace in themselves, cannot fail to have a special interest because of their association with, and bearing upon, an epidemic of typhoid unique for its magnitude in the annals of British medicine. As it will be assumed in that which is to follow that this epidemic was the result of the drinking of water poisoned by typhoid material, it is necessary in the first place that I should give at least a sketch of the facts that this assumption is based upon. For five-and-thirty years, during which I have resided in the town, Maidstone has enjoyed a reputation favourable for exemption from typhoid, for the death-rate from this disease during 1879-96 (the eighteen years of my occupying the position of Medical Officer of Health) has been only 121 per million, against the following rates for England and Wales and Kent respectively:

England and Wales { 1871-75 = 374; 1876-80 = 277; 1881-85 = 211; 1886-90 = 179 } *Kent* { 1871-80 = 330; 1881-90 = 180 }

Moreover, during the first seven and a half months of 1897 only five cases were reported, the last of these being an importation from Gibraltar, so that the news of a serious outbreak, which reached me whilst I was away on the Continent for my summer holiday, came as a complete surprise. The first cases to be notified were 2 on Saturday, September 11, next day 4 more were notified, and on Monday another, making a total of 7 in three days. This was the first warning of the coming storm. Inquiries were immediately set on foot to trace any possible connection with milk or other sorts of food. At this time no suspicion attached to the water-supply, but as on the 16th 27 fresh notifications were received, then the water began to be suspected. On the 17th 26 more cases occurred, making altogether 64 notified in six days. These having been plotted out upon a spot map, it soon became apparent that the incidence of the disease was confined to certain parts of the town, practically to the entire exclusion of all districts excepting those that were supplied by a particular branch of the public water service.

Maidstone derives its water-supply from three sources, as follows:

1. From chalk springs at Cossington.
2. From chalk springs at Boarley.
3. From greensand springs at Farleigh.

The affected districts coincided absolutely with the Farleigh area of supply, and as time went on this feature in the distribution of the disease became more and more noticeable, as it were dissecting the town street by street and house by house, in accordance with the distribution of the Farleigh water—so accurately, indeed, that as a fact one small district, to which I shall presently refer as the "Special Area," comprising 338 houses, which in the first instance we had been led to believe was supplied with Cossington water, by the incidence of this disease was discovered in reality to have been supplied for the time being, through an oversight, with Farleigh water. Naturally, as time went on, a certain amount of spreading took place into other parts of the town by the casual drinking of the Farleigh water by the inhabitants of the other two water areas and by personal contagion, but the main features of its territorial distribution were maintained to the end, as is demonstrated by the following completed table of incidence:

Cossington Supply.

District.	Houses.			Persons.		
	Number.	Invaded.	Per cent.	Population.	Attacked.	Per cent.
To West Maidstone	585	12	2·05	2,925	19	0·64
To East Maidstone	86	7	8·14	430	10	2·32
Total	671	19	2·8	3,355	29	0·86
Boarley Supply.						
To West Maidstone	—	—	—	—	—	—
To East Maidstone	1,410	63	4·46	7,050	69	0·97
Total	1,410	63	4·46	7,050	69	0·97
Farleigh Supply.						
To West Maidstone	1,618	435	26·8	8,090	673	8·32
To East Maidstone	1,960	547	27·9	9,800	776	7·92
Special Area	338	95	28·1	1,690	134	7·92
Total	3,916	1,077	27·5	19,580	1,583	8·08
Grand Total	5,997	1,159	19·32	29,985	1,681	5·60

From which we learn that there are 5,997 houses in Maidstone supplied by the Water Company—671 of these with the Cossington water, 1,410 with the Boarley water, and 3,916 with the Farleigh water. Of the 671 in the Cossington area, 19 (= 2·8 per cent.) were invaded; of the 1,410 houses in the Boarley area, 63 (= 4·46 per cent.); and of the 3,916 houses in the Farleigh area, 1,077 (= 27·5 per cent.) were invaded. Then as regards persons: out of a population of 3,355 in the Cossington area, 29 (= 0·86 per cent.) were attacked; of the 7,050 in the Boarley area, 69 (= 0·97 per cent.); whilst of the 19,580 in Farleigh, 1,583 (= 8·08 per cent.) were attacked.

Furthermore, when we break up the districts of supply into sub-districts, we notice the rates of invasion of houses and attacks upon the respective populations are

as irregular as can be, so far as they relate to the Cossington and Boarley areas, but just the reverse in their relation to the Farleigh area. For instance, the rates of invasion of the houses in the Cossington sub-districts and the Boarley district were 2·05, 8·14, and 4·46, whereas in the Farleigh district they were 26·8, 27·9, 28·1. Mark you, the *special area* which (as already said) was originally supposed to have received its supply from the Cossington springs by the rate of the invasion of the houses led to a special investigation, whereupon it was discovered that, owing to a temporary exigency of the service, this special area for the time being was supplied from the Farleigh springs, with which service, as you see by the rates, it exactly corresponds. In the same way the same contrasts are manifest in regard to the persons attacked; whilst in the Cossington and Boarley districts the rates of attack vary tremendously (0·64 per cent., 2·32 per cent., and 0·97 per cent.), in the Farleigh they are practically identical (8·32 per cent., 7·92 per cent., and 7·92 per cent.), clearly showing that whilst the agent of mischief in the Farleigh district had been equal and uniform in its operation, such had not been the case in the Cossington and Boarley districts. In other words, the cause of the mischief had been the *habitual* drinking of the Farleigh water by the inhabitants of the Farleigh district, and the *casual* drinking of the Farleigh water by the inhabitants of the Cossington and Boarley districts.

I think I have now said enough to justify the suspicion which fell upon the Farleigh water, and, the suspicion having been aroused, samples were collected for analysis on September 19, 20, and 25. I may here remark that this Farleigh water is itself a compound water, the joint produce of a number of springs derived from the Hythe beds of the lower greensand situated right and left of the river Medway, which is their natural drainage outlet. Composed simply of subsoil water, these springs emerge at the junction of the greensand with the underlying Atherfield clay, and have been in use for the public water-supply for very many years. In the pursuit of my official duties I have made periodical analyses of the joint product of these springs for a space of twenty-five years, but until the time of the epidemic never of the individual springs separately. These periodical analyses have shown, in later years at all events, very great constancy of composition, so that we had come to regard the Farleigh source as thoroughly trustworthy. We have still another public water-supply in Maidstone, the property of the town, as distinct from the property of the Water Company, called the Conduit Supply. This comes from a source exactly similar to that of the Farleigh springs. A long series of periodical analyses of this water shows its composition to be practically invariable. For this reason I have made the Conduit water serve as my "*local standard*," for purity of greensand, or, as we say locally, Ragstone water, to which all waters in our neighbourhood derived from that formation, if pure, should strictly conform. As all the conclusions relating to the analyses which I am now about to submit to you are based upon a comparison with this local standard, I have inserted the figures relating thereto in the first column of the table of results of the analyses. Before entering upon a consideration of the figures of the analysis, it is proper I should state that, to the best of my judgment, the poisoning of the water commenced about August 17, and terminated about September 25; that it was at its worst during the last four

days of August and the first four days of September; and, further, that, judging by the dates of attack, and making allowance for the period of incubation, the violence of the epidemic had long passed when the first sample of water was collected.

Analyses of the Farleigh Waters.—The periodical analyses, which had formerly been made once a fortnight, for reasons of economy were cut down by the borough authorities to once a quarter, and the last occasion on which the Farleigh water was analysed previously to the outbreak was on June 25, with the following results:

	Standard.	June 25.	
Total solids	32·890	33·900	grains per gal.
Chlorine	2·300	2·500	,, ,,
Nitrogen as nitrates...	0·466	0·570	,, ,,
Free ammonia	0·005	0·010	pts. per mill.
Albuminoid ammonia	0·015	0·010	,, ,,
Oxygen absorbed in a quarter of an hour	0·008	0·009	grains per gal.
Oxygen absorbed in four hours ...	0·018	0·012	,, ,,
Total hardness	17·400	16·800	,, ,,
Permanent hardness...	6·500	8·000	,, ,,

The main difference from the standard was 1 grain per gallon in excess of total solids, 0·2 of a grain chlorine, and 0·1 nitric nitrogen. Though the total hardness was a shade less, the permanent hardness was 1½ degrees more, in consequence of the increased nitrates. From a consideration of these figures, I think we shall agree that the variations from the standard were but trifling, and in no way calculated to create alarm. Unfortunately, the quarterly arrangement was the reason of no further analysis being undertaken until after the outbreak—in fact, not until September 19, when suspicion had fallen upon the water. Then, of course, careful inspection of all the springs that contributed to the Farleigh supply was immediately set on foot, and samples collected for analysis from each of them. Meanwhile, the most suspicious of the springs, so far as local appearances went, were cut off. The results of the analyses of these various samples, together with the corresponding figures of the local standard, are set forth in the table on pages 154, 155, a comparison with which shows the *total solids* to be in excess in almost every case, sometimes to a considerable amount. The *chlorine*, though never a large item, shows excess in a few instances, but it is as often low as it is above the standard. *Nitrogen, as nitrates* and nitrites, in every case but one shows excess, often very great excess. *Free ammonia* was either absent or exhibited a mere trace. *Albuminoid ammonia*, in all but seven instances, was an inconspicuous figure; in five cases it showed in considerable, but never in remarkable, excess. *Oxygen consumed* was never in substantial excess. The *hardness*, especially the *permanent hardness*, was practically always in excess, except in the case of the Ewell springs. *Phosphoric acid* showed considerable or large excess in only about four instances.

Physical Appearance.—The Tutsham-in-Fields water alone was conspicuously at fault. In about three other instances there was noticeable greenish opacity, but nothing to attract particular attention. The appearance of the *residue* both before and after ignition in many instances gave occasion for remark. By far the most

important and most frequent variation from the standard was the excess of nitrogen as nitrates, and I invite your special attention to this feature of the analyses for reasons which will be more apparent by-and-by.

For the present I must leave the chemical aspect of the question, and ask you to follow me in the consideration of certain meteorological events that appear to have had a most important bearing upon the cause and method of the pollution of the water. For many years past I have recorded the daily fluctuations in the level of the subsoil-water; these observations led me to discover the occurrence of certain unusual features concerning the fluctuations that occurred during last August, exactly corresponding with the occurrence of the typhoid outbreak. These I will endeavour to make clear to you. In diagram No. 1 three sets of facts are exhibited by a graphic method drawn to scale. In the lower part we have the daily record of the subsoil-water in feet; upon this, in black, is seen the rainfall in inches. At the upper part of the diagram are recorded the cases of typhoid referred to the dates of attack.

For the present it is my desire that your attention be confined to the lower part of the diagram, to the records of the subsoil-water levels and the rainfall, and the points I more particularly wish to discuss with you are: the general contour of the ground-water level, the factors that are instrumental in raising or depressing the level, and the interpretation of certain abnormalities which, as we shall see, exactly coincide with, and, as I shall endeavour to show, were instrumental in causing the epidemic. In the first place you will observe that the ground-water level was at its highest in February and at its lowest in November, that it exhibits, speaking generally, a more or less gentle and uniform fall during the intervening eight months, with certain interruptions about which I shall have more to say by-and-by.

The rainfall, which, by the way, was remarkably scanty—in fact, the lowest recorded since 1870, being only 19·73 inches, against a twenty years' average of 25·9—was distributed in such a manner that a great part of June, the whole of July, and the first six days of August—the hottest part of the year—were almost rainless. Of course, the level of the subsoil water is in great measure, but by no means wholly, dependent upon the rainfall. Two other factors have great influence upon it, viz., evaporation, caused by sunshine and wind, for one; and plant-life, causing absorption and dissipation, for another. A critical examination of this and similar diagrams relating to other years affords evidence that the water-level is usually at its maximum height during the early months of the year, and commences its descent in April, after the vernal equinox, when plant-life begins to be active; and the sinking continues through the summer solstice so long as light abounds and plant-life continues vigorous, even in spite of rainfall, until the autumnal equinox, when the earth enters the winter solstice at the end of September. Then, or at the beginning of October, a rise usually sets in, though such was not the case in 1897, for we find the descent continued till November 28—but last year was altogether a most exceptional year. Of course, this order of events is liable to a temporary interruption, and the curve is subject to more or less distinctly marked irregularities by the occurrence of rain, and it is to the minor details of this matter I would now ask your special attention. Let us begin with the year. Between January 4 and 10 there was a pretty consider-

able rainfall, and its effect upon the water-level can be traced in the rise commencing on the 8th; during the last two days in January and the first five days of February a large mass of water fell, and the consequent effect is far more obvious; up went the subsoil-water till it reached its maximum on February 11; a small, sharp and temporary rise followed a sudden and copious rainfall during the first two or three days of March, but, in spite of the fact that March, with seventeen days of rain, proved a wet month, the sun having gained power, a check was set upon the further rise of the ground-water. During April, its fourteen days of showery weather notwithstanding, down went the subsoil-water, chiefly owing to the vigour of plant-life, so that by the end of May, though there had then occurred a whole week of heavy rain, the water-level continued to sink rapidly. On June 8 there came a very heavy fall (nine-tenths of an inch), all within a few hours, but, mark you, only a slight impression is produced. The rest of June, and practically the whole of July, and the first six days of August, were rainless; on August 7 and 8, two most momentous days for Maidstone, something less than half an inch of rain fell, but, as a consequence, behold the prodigious rise in the subsoil-water level. On the 15th and 17th there was more fall, and the level continued to rise. On the 18th still more rain, but mark that, instead of a further rise, the ground-water began to descend, and continued to do so in spite of more rain on the 20th, 24th and 26th, the descent being as rapid as the previous ascent had been, even though the rainfall on the 26th, on one day alone, was greater than that which fell on the 7th and 8th together, when such an amazing effect had been produced. During the last three days of August and the first day of September about three-quarters of an inch of rain produced another considerable, though less conspicuous, rising, which, like its precursor, soon subsided. After this a marked rise could not be maintained even by the considerable rains of September 6, 18 and 19, nor restored by one of the heaviest rains of the year, on the 29th.

Now let us look into the explanation of all this: Geologically, Maidstone is situated at the junction of the lower greensand with the Atherfield clay, where the constituents of the two rocks mingle, so that our soil and subsoil consist of sandy or clayey loam, according to the circumstance of the exact situation. At this point it is essential I should remind you of a remarkable property exhibited by clay rocks. I allude to the circumstance peculiar to clay—that it expands in the moist condition and largely contracts when dry; moreover, when greatly desiccated, it becomes hard as a clinker; as a consequence, in times of drought, under this latter condition clay soils are liable to become fissured; and as a fact, established by personal observation, during last summer's drought I found wide cracks into which a stick could be thrust 3 feet deep into the subsoil without reaching bottom; how deep the cracks went I have no idea. With this condition of things, it is obvious that the rains of August, instead of penetrating into and being absorbed by the soil and subsoil could, and would tend to find a direct road through the cracks straight away into the subsoil springs, accumulating in the first instance in the cracks between the desiccated fragments without being absorbed into the mass of the soil, thereby quickly, though temporarily, raising the level of the ground-water, that is to say, in the spaces between the fragments of the cracked soil; but so soon as absorption of the water into the

mass of the soil took place, the adventitious rise would give way to subsidence, and thereby the water level would sink as quickly as it had risen. About a fortnight later these phenomena were repeated, with this difference: we find that though the rainfall was much greater, the effect was much less, because the surface induration of the clay fragments having already been overcome by the earlier rains, capillary absorption had in a measure been restored to its normal condition. In connection with this branch of the subject there are many interesting points of detail that one would like to dwell upon, such as a comparison of the various effects of similar rainfalls in different conditions of the soil. For example, compare the rain of August 7 and 8 with the almost exactly similar fall on September 18 and 19, producing in the earlier case a tremendous rise, because of the dry, cracked state of the soil—in the later case, when the soil was moist and the cracks had closed up, producing no sensible effect at all. But time presses, and we must pass on to a consideration of the upper part of the diagram. There we have depicted the cases of typhoid according to their dates of attack. In order to make the occurrence of the two sets of events—that is to say, the pathological and meteorological; the typhoid and the movements of the ground-water—comparable, a proper allowance must be made for the period of incubation of typhoid: fourteen days is reckoned an average period, but it varies considerably. In addition to the fourteen days for incubation, a day or two must be allowed for the water to get to the consumer, so that in the diagram I have set back the typhoid manifestations sixteen days. This should bring the two sets of events approximately into relation as regards time. It is practically certain that in the mass of cases recorded there must be some with short incubation; of course, it is impossible to distinguish between these and those of average incubation, so that the few scattered earliest cases as they appear in the diagram are those having short incubation, and consequently set too far back. Be that as it may, except for the two or three earliest cases, the commencement of the epidemic exactly coincides with the summit of the first rise, and the acme of the great mass of the disease coincided with the summit of the second rise. These coincidences are more than curious; surely they stand related to one another as cause and effect.

Allow me to recapitulate the facts: We have a subsoil-water stored beneath a loamy clay, situated in a highly-cultivated district, where heavily-manured crops are grown, and where many people are employed in the cultivation and gathering of fruit and hops. The surface is necessarily bestrewn with effete organic matter, and exposed to casual pollution by the workpeople employed. An unusual drought occurs, giving rise to cracks in the soil and subsoil. We have physical evidence of the rapid passage through to the subsoil water-level of the surface-water derived from the rains of August 7 and 8. Chemical analyses bear evidence that the ordinary natural processes of purification are in abeyance. A six days' pause from rain follows; polluting specific matter is retained in the cracks of the soil and subsoil hot from the summer's sun; incubation of the putrefying and specific organisms takes place in the dark, moist subterranean recesses, the cultivation process being promoted by the showers that fell on the 16th, 17th, 18th, 20th. Then comes another pause, during which an abundant crop of organisms is produced, followed in six and more days later by heavier rains, which carry the pathogenic products into the ground-water, out by the springs,

straight away into the public mains, and, as a consequence, the epidemic immediately follows.

It appears to me the chain of causation and effect is complete. I should like to make a further use of these reflections. We all know what a difficult and responsible problem the interpretation of a water analysis for sanitary purposes often is, and anything that will help to a rational understanding of the natural causes of dangerous pollution is sure to be welcome. Moreover, if by an application of the rationale we can lead up to a natural generalization, it cannot fail to be of some use. Now, the diagram before you exhibits an ideal section of soil and subsoil, such as we have been contemplating. The surface is supposed to have been polluted by the deposit of effete animal matter, and the idea is to represent in outline the natural processes concerned that tend for and against the purity of the water that accumulates and flows beneath. At the outset, I would remind you that three distinct sets of operations are engaged in the protection of ground-water against organic pollution. First, there is the action of putrefying organisms; second, the action of nitrifying organisms; and third, the action of plants. Crude complex organic matter is first broken up into simpler organic matter; this is then mineralized into nitric, nitrous, and carbonic acids, and finally the nitrates are removed by plants. When these three operations are fully accomplished, water, however much polluted in the first instance, in the end is rendered pure and wholesome. In the main, the several operations are executed at successively deeper situations in the soil, and for convenience we may contemplate three distinct zones, each the seat of its appropriate function. The uppermost we may designate the "danger zone"—where the putrefying organisms are at work, converting the crude animal matter into leucine, tyrosine, toxalbumin, etc. The next we may style the "risky zone," where mineralization goes on, but where conversion is not complete, where the roots of plants take up the mineralized products, but also where the harmless and the poisonous products mingle. Beneath this we come to the "safe zone," where the water it contains is found to have been purified not only from all organic matter, but also more or less completely of all of its nitrogenous products. In Nature, of course, the situation of these zones is not fixed, but varies according to the exigencies of the climate, as I have attempted to portray in the diagram. It follows, therefore, if the foregoing propositions are correct, that the presence of an abundance of nitrates in subsoil-water in most cases is significant of risk, because it shows the water to be derived from the "risky zone," and implies the possibility of its coming from the "danger zone," and the certainty that it is, at least in an unrenewed condition, charged with the products of oxidized organic pollution. Remember we are contemplating subsoil-water; and I would here remind you that there is nothing to show that pathogenic live organisms are acted upon by the nitrifying organisms. For aught we know to the contrary, these latter only act upon dead organic matter; and so far as cholera and typhoid organisms are concerned, such protection as the soil can afford is rather of the nature of filtration than destruction. I now come to the last point I wish to discuss with you; it is one that has arisen out of the ground-water observations. We are all familiar with the circumstance that disorders pro-

pagated by the fæcal pollution of water, such as cholera and typhoid, are very commonly, though not always, liable to be preceded by what is called "*premonitory diarrhœa.*" This association, because of its uncertain occurrence, seems to be due to some, as yet undiscovered, extrinsic cause. In our case the epidemic *was* preceded by premonitory diarrhœa. Suddenly, before the earliest typhoid attacks occurred, the town was flooded by complaints of violent diarrhœa (see diagram No. 2) of quite a different sort from ordinary summer diarrhœa—in fact, more like that produced by poisoning. I have endeavoured to obtain accurate information concerning these occurrences, and certain of my medical friends have furnished me with particulars which show a correspondence as respects time between the symptoms of this illness and the first rising of the subsoil-water; but they also show that as the typhoid epidemic advanced the diarrhœal attacks subsided, from which it is but natural to infer that the water drunk by the people of Maidstone contained, temporarily only, a poisonous material capable of producing diarrhœa. Now, I suggest that toxalbumin was the cause, and that this material, having accumulated on the surface of the soil and within the danger zone, was washed down by the early rains of August in an unaltered condition through the risk zone without being nitrified, and so into the water that was being drunk during the early and middle part of August. Having regard to the physical condition of the soil and subsoil at this time, it seems quite possible; this material being soluble, we can readily understand that it would be easily and quickly washed through the subsoil, and that its effects would be spent in the early stages of the epidemic. On the other hand, the typhoid bacteria, being particulate and probably few at the start, might lodge in the dark recesses of the warm subsoil, there multiply by incubation during the interval between the two uprisings of the ground-water, and eventually be flushed forward by the rains that produced the second rise. This, it appears to me, is a reasonable explanation of the order and character of the events, of the premonitory diarrhœa, and the subsequent explosive outburst of typhoid. Though I have no physical evidence to substantiate it, this theory accurately fits in with the observed facts. The difficulty of obtaining experimental evidence, I imagine, would be very great, nevertheless; and I think you will agree with me the problem is of sufficient interest to deserve investigation from a chemical as well as an etiological point of view.

In this record of my experiences you will readily find subjects for discussion; in order, however, to give a practical turn to the matter, allow me to gather together in the form of propositions some of the principal points:

(1) That the recorded facts unmistakably inculpate the Farleigh water with the cause of the epidemic, and that the result was brought about by the unusual meteorological circumstances in the manner suggested.

(2) That the medical history of the epidemic indicates the presence of two sorts of poison in the Farleigh water, the one of a chemical toxic nature causing the "premonitory diarrhœa," another of a biologic nature, causing typhoid.

(3) That the most conspicuous features of the chemical analyses are (*a*) a large excess of nitrogen as nitrates, (*b*) a comparatively small excess of albuminoid ammonia, (*c*) a remarkably small amount of oxidizable matters.

(4) That this occasion affords another illustration of the impossibility of formu-

lating an artificial standard for the chemical constitution of potable water that can serve as a basis upon which to found a correct judgment as to its sanitary wholesomeness without other considerations being taken into account.

(5) That a better, simpler, and more natural basis is attained by the establishment of local standards.

(6) For this purpose, especially in the case of public water-supplies, it is essential that frequent analyses be made at short intervals, at all seasons, with or without bacteriological observations.

(7) That continuous observations should be made and records kept respecting the meteorological phenomena, especially the movements of the subsoil-water and the rainfall, these being desirable in every case, but absolutely necessary where the supply is derived from the subsoil.

(8) That apart from ordinary considerations due to the natural mineral constituents, a water that is of stable composition is wholesome; on the other hand, instability of composition, whatever the fluctuations may be due to, denotes risk.

(9) For the reasons adduced, the presence of nitrates or nitrites among the mineral constituents, unless there be some local geological explanation thereof, is indicative of risk—past, present, or future.

(10) That it is desirable that research should be directed to the chemical and physiological processes associated with filtration; among other things, to determine what happens to living pathogenic organisms. Are they attacked and destroyed under any, and, if so, what, circumstances?

In bringing this paper to a close, I must apologize for having spent so much time over the physical facts; but, if I am not mistaken, they lead to considerations that have not received the attention they require. According to my view, it has been too much the custom to look upon the analysis of water as having for its sole object the detection of pollution dangerous or injurious to health, whereas it ought to be the chief function of the sanitarian, whether he be chemist, medical officer, or water engineer, to prevent water from becoming dangerous or injurious, to anticipate pollution, and give warning of the approach of such. Surely the first step in the realization of this purpose is to ascertain the mechanism, so to speak, of its occurrence. This communication is intended as a contribution to that end, and, if in any sense successful, I hope it may stimulate to further observations, and perhaps assist in the interpretation of the chemical results of the analysis of water for sanitary purposes.

Discussion.

The President said that all of those present had probably to some extent familiarized themselves with the general subject of the Maidstone epidemic and its relation to water-supply through the abstracts of the reports of Dr. Adams and Dr. Washbourn which had appeared in the press. He was sure, however, that this paper would give them a much clearer and more instructive idea of the subject. The paper, no doubt, raised some debateable points; but however different individual opinions on some of the points might be, it would be generally agreed that Dr. Adams deserved hearty thanks for the very lucid way in which he had presented the facts

and views set forth in the paper, and that he had rendered very great service to the town of Maidstone by his work in the matter. The connection between the rainfall, the subsoil water-level, and the outbreak of the epidemic had been very lucidly demonstrated, and the chain of evidence all through seemed to be complete. The latter part of the paper, however, contained matter which at the present time might be regarded as almost new. Formerly the general opinion was that the danger from drinking polluted water was due actually to poisonous organic matter. Gradually that was given up, and the dangers attributable to drinking polluted water had been generally recognised to be due, not to dead organic matter, but to living organisms, which exercised pathogenic functions within the system. According to the view which Dr. Adams put forward, it was suggested that there was something in the older theory, after all, and that actually poisonous substances (presumably produced originally by micro-organisms, but already existing in the water) might be introduced —"in bulk," as it were—into the human system, instead of being developed by the bacteria after the consumption of the water. If this were really the case, one would expect to get some evidence of it in the shape of a rise in organic nitrogen; and for the examination of the view held by Dr. Adams, it was certainly unfortunate that there was not an analysis of the water at the earlier period, during which these substances might have been present, and when it could have been seen if there was an excessive quantity of albuminoid ammonia. But thanks to the zealous desire of the Maidstone Corporation to exercise small economies in order to keep down the rates, they were deprived of what might have been valuable information in the examination of this particular theory. What Dr. Adams had said with regard to local standards was most important, and also what he had said as to the very great value of nitrates as an indication of pollution, the latter point being noteworthy in view of a recent matter in which Dr. Adams had been concerned. Dr. Adams had lately condemned a well at Maidstone which was shown by chemical analysis to be grossly polluted, and which was close to drains in the neighbourhood of several typhoid-infected houses. The magistrates sought confirmation of Dr. Adams's opinion, in view of its being challenged, by an appeal to the Government chemists, who in their report pointed out that the water as to albuminoid ammonia and oxygen absorbed compared favourably with water drawn from the London water companies, but also that it contained 1·8 grains of nitric *nitrogen* per gallon (equivalent to nearly 7 grains of N_2O_5). They stated, certainly, that this proportion of nitrates was "rather high," but that, having regard to the character of the mineral constituents of the sample, this did not indicate that the water was exposed to organic contamination; and they expressed their opinion that the use of the water for potable purposes was not likely to prove injurious or dangerous to health. A comparison of the water with the "local standard" for unpolluted water in the neighbourhood would surely have rendered such a report impossible. Dr. Adams had said nothing in the paper about the bacteriological side of the investigation of the Maidstone epidemic; but Dr. Washbourn was present, who had worked side by side in the matter with Dr. Adams, and any remarks which he might make from this point of view would be listened to with interest.

Dr. J. W. Washbourn said that he thought it would be generally accepted by

the Society that this epidemic was produced by the Farleigh portion of the Maidstone water-supply. The evidence which Dr. Adams had brought forward in favour of that view was most conclusive. Chemical analysis had shown beyond question that the water had become polluted in some way or other with organic material, and the only question likely to be discussed in this connection was as to whether the organic material was of a vegetable or animal nature. With regard to the bacteriological examination, he might say that an examination was made of a large number of the springs making up the Farleigh supply. The first question to decide was whether the water contained any typhoid bacilli. The result of the examination in this direction was entirely negative, and this he attributed to two facts. In the first place the examination was, as had been pointed out by Dr. Adams, undertaken at a time when it was very likely that the typhoid bacilli had disappeared: and in the second place, the examination was not commenced until the epidemic was at its height, by which time it was very likely that the pollution had passed off. As the incubation period of the disease was about fourteen days, the examination ought to have been made at least a fortnight, if not three weeks, earlier. That was probably one reason for the negative nature of the results obtained. The other reason was no doubt the fact that the methods at present available for detecting the typhoid bacillus in contaminated water are very imperfect. He did not know of a single instance in which water suspected of conveying typhoid fever had been definitely proved to contain the typhoid bacillus. On several occasions it had been stated that typhoid bacilli had been found in drinking-water, but most of these examinations were made at a time when the methods adopted for distinguishing the typhoid bacillus were not sufficient to distinguish it from other allied bacilli. The best instance in which an examination with the object of detecting the typhoid bacillus seemed to have been carried out according to modern methods was that of experiments made by Remlinger and Schneider, who found typhoid bacilli, or at any rate bacilli having the characters of the typhoid bacillus, in a large number of samples of water and soil. In fact, the very large number of instances in which they found the typhoid bacillus looked suspicious, and the account given in the journal of the Pasteur Institute of the character of these bacilli was not sufficiently detailed to enable definite conclusions to be drawn. The next step in connection with the Maidstone water was to examine and enumerate the bacteria present. The number of bacteria found in water was of itself not of very great importance, though he thought that if a water was constantly found to contain a large number of bacteria, it might be taken as certain that it was polluted, not with animal matter necessarily, but with material of some kind from the surface. The surface of the soil contains a large number of bacteria, but the further down one goes, the fewer one finds, until the deepest layers are found to contain no bacteria at all. If a water was pure, it would contain very few bacteria, but a water might contain only a few bacteria and still be liable to contamination. On the other hand, a fairly large number of bacteria might be found in a water which was not polluted. Water that had been stagnant for some time in a well would, when it was first pumped up, contain a large number of bacteria, the fact of the matter being that the bacteria had sunk to the bottom, forming a sediment which would be drawn up by the first pumping. In judging the purity of a water from the

☞ All results are given in grains per gallon, except Free and Albuminoid Ammonia, which are in parts per million.

number of bacteria it contained, it was necessary to be very careful, although, as he had said, if a large number of bacteria was constantly found, it might be taken that the water was bad. The character of the bacteria, however, was of the greatest importance. No doubt waters from different sources had their own special bacterial flora, but certain bacteria might enter into water from animal excreta, these bacteria mostly belonging to the group of organisms known as *Bacillus coli communis*. These bacilli were found in large numbers in the intestinal contents of almost all animals, and they could be distinguished from somewhat similar bacteria which were present in pure water. The bacteria present in pure water which resembled coli were bacteria belonging to the *Aquatilis sulcatus* group. They could be distinguished quite readily from coli bacilli, among other points, by the fact that they did not grow at the temperature of the body, or only grew very feebly at that temperature. The coli bacilli, on the other hand, grew readily at this temperature.

The intestinal contents of animals, human or otherwise, contained a large number of different varieties of coli, some coagulating milk quickly and some slowly, some producing more acid than others, and so on. In fact, in all intestinal evacuations, there were to be found what were called *a*-typical coli bacilli, which differed from the ordinary text-book description in some minor points. There was no evidence that coli ever occurred in water that had not been contaminated with animal matter. Water contaminated with vegetable matter and upland waters did not contain coli, as far as was known. Whenever the coli bacillus was found in any numbers, it meant contamination with animal excreta. In saying that water contained coli bacilli, he meant in fairly large numbers, since animal excremental matter was very widely distributed, and consequently coli bacilli were also widely distributed; so that in examining a large quantity of water, one might now and then meet with one or two colonies, the occurrence of which would not be of any significance, but due merely to accidental causes. A large number, however, say 60 per c.c., would definitely show a water to be contaminated with animal excreta, such as he had found to be the case in one of the springs which supplied the Farleigh water. The presence of these coli bacilli simply meant that the water was contaminated with animal excreta. It did not necessarily indicate human excreta, but it did indicate that the water was contaminated with animal excreta, and that it was thus liable to contamination with typhoid material. There was one other point with regard to the coli bacillus, namely, the question of its pathogenic properties. There was no function possessed by the coli bacillus that varied to a greater extent than its pathogenicity. Some coli bacilli had strong pathogenic properties, while others had no pathogenic properties whatever, so that this factor was of no value at all in determining whether any particular organism belonged to the coli group or not. The only point on which he disagreed with Dr. Adams was in regard to the wave of diarrhœa which preceded the typhoid epidemic. He had no doubt whatever that Dr. Adams's explanation of the rise in the subsoil water was correct, and that the water had become contaminated with typhoid virus in the way which Dr. Adams had described, and he (Dr. Washbourn) believed that the water at the same time became contaminated with the virus that produced the premonitory diarrhœa. But he believed that this virus was a living micro-organism and not a chemical poison. A large quantity of a toxalbumin would need

to be present in order to produce so much diarrhœa, and he did not know of any toxalbumin that would produce such an effect in small quantities. The more one knew about cases of "food poisoning" the more one was inclined to look upon them as due to the ingestion of bacteria, and not of toxines. He believed that the Farleigh water was contaminated both with the specific typhoid bacillus and with some form of bacterium which would produce diarrhœa, and that the reason why the diarrhœa occurred earlier was simply that the incubation period of the diarrhœa was shorter than that of typhoid fever.

Dr. CHILDS, rising in response to an invitation from the President, said that the subject of subsoil water was one of which he had made a special study in connection with the prevalence of typhoid fever in the city of Munich during the last forty years. It would be difficult, however, to make any comparisons between the data that came from Munich and those obtained from a study of the epidemic at Maidstone, though there was this analogy between them, that in Munich, as well as at Maidstone, the relations between the movements of the subsoil water and the rainfall seemed to be exceedingly irregular. It could not be predicted, from a previous heavy rainfall, whether there would be a large rise in the subsoil water or not. It depended upon a good many other conditions, such as those which had been mentioned by Dr. Adams, and also upon the previous rainfall. If the subsoil had become water-logged, the rain falling upon it would cause a considerable rise; but if there had been a drought, the subsoil itself would act as a sponge, and there might be little or no rise. The whole question required a tremendous amount of elaboration and study before one could speak of these relations with any accuracy. With regard to the relations of the subsoil-water level to typhoid epidemics, these had been very distinctly established in Munich, whilst, contrary to the experience in our own country, the Munich authorities considered that there was no relation at all between the actual drinking of the water and the prevalence of typhoid fever. Pettenkofer and his school had long been convinced of this, and, as time went on, seemed to become even more convinced still. But the conditions of the city of Munich were exceptional, and different from those usually prevailing in this country. And although the revelations obtained there were rather extraordinary, and tended to shake one's faith in the convection of typhoid by water, they could not be taken as analogous to the results generally obtained in this country. His own personal conclusion was that there were many different ways in which typhoid fever might be conveyed. The evidence obtained in this country as to the water convection of typhoid was so strong, and reached such high degrees of probability in many instances, that he thought it must be held to be conclusive, in spite of the different ideas held by such a great authority as Pettenkofer. He agreed with the President in feeling grateful to Dr. Adams for emphasizing the necessity for the establishment of a local standard of purity, and for proper inspection and supervision of the sources of water-supply and their surroundings; which latter point he (Dr. Childs) regarded as of primary importance.

Mr. HEHNER said he was sure that Dr. Adams would have the Society's sympathy in the fact that, after so many years of service at Maidstone, he should have been confronted with the recent typhoid epidemic, coming as it did after many years of labour in the interest of the health of the district. On the other hand,

Dr. Adams must be congratulated on the exceedingly interesting observations which he had made on the subsoil water of the district, which, though not appearing at first likely to lead to any useful result, had now been rewarded by the brilliant deductions he had been able to make with their aid. The long series of analyses of samples of water showed conclusively that, with one exception, they were all polluted to a large extent. Anybody conversant with water analysis, and anyone who had urged, as he (Mr. Hehner) had done many years ago, the importance of not judging from arbitrary standards, but taking as a basis the composition of the pure water of the district, would agree that there was overpowering and conclusive evidence in these analyses that the samples were polluted with a nitrogenous substance which yielded nitric acid, and hence almost certainly with animal matter. With this was to be compared the fact that even in the able hands of Dr. Washbourn bacteriology had failed in almost every case to afford evidence of pollution. He (Mr. Hehner) admitted, of course, the great difficulty of the task which had been given to Dr. Washbourn, who had had to examine the water so long after the outbreak; but Dr. Adams had also been in the same position. He (Mr. Hehner) was puzzled by some of the figures given by Dr. Adams, because, if the history of the outbreak as gathered from the newspapers was correct, the pollution was due to the accidental contamination of the soil by a limited number of people, and it was difficult to understand how on so many days, extending over some months, there should have occurred such a notable increase in the nitric acid, an increase which was found, not in one sample only, but throughout the series. The Farleigh water was supplied to 20,000 inhabitants, the average supply being about 20 gallons a day per head; consequently an increase of 110 per cent. of the normal proportion of nitric acid meant a daily increase of 126 lb. of nitric acid, which over several months would represent a good many tons, and it was scarcely possible to think that a chance pollution on the surface should have been able to produce such immense chemical results. Dr. Adams's very ingenious distinction between toxalbumin poisoning and actual bacterial poisoning struck him as somewhat bold, because there appeared to be no basis for such a theory, except the inference that premonitory diarrhœa occurred immediately before the epidemic, and before the bacilli were likely to act, a suggestion, however, which was not entertained by Dr. Washbourn, who thought that even the poisoning usually attributed to ptomaines in tinned goods was due to bacterial causes. There was, however, a sharp, or at any rate a fairly sharp, distinction between strictly chemical poisoning and bacterial poisoning. The effect of chemical poisoning was far more rapid than would be expected, if bacteria had first to incubate and multiply. But as a matter of fact the products of living organisms were capable of producing powerful toxicological effects. It might be quite possible for even a very small quantity of a substance of the nature of toxalbumin to produce the diarrhœa which had been observed.

Mr. ALLEN said that Dr. Adams had shown very clearly the great value to be attached to a conclusion derived from the quantity of oxidized nitrogen present in water. The Maidstone epidemic had been caused unquestionably by water that did not contain more than the normal proportions of free and albuminoid ammonia, etc., but contained a large proportion of nitrates. It was a fact to be greatly deplored,

that the significance of oxidized forms of nitrogen in water was systematically ignored by the writer of one of the most popular and widely-used works on water analysis. In water analysis it was impossible to have too many data upon which to base an opinion. He would say, obtain as many chemical factors as possible, and, if bacteriology was likely to be of service, make use of it also. He would not limit the analysis of water to any small number of tests, but would have as complete an examination as possible, so as to be in a position to regard the matter from every point of view. With regard to the instance in which the Government chemists, having undertaken to report upon a sample of water from a Maidstone well which was surrounded by houses infected with typhoid fever, stated that the water contained 7 grains of nitric acid per gallon, and yet was not even *liable* to contamination, he thought it was a pity that they should have gone out of their way to express an opinion on a point wholly outside their range of information, and not warranted in any way.

Mr. CASSAL said that up to the present full chemical analysis, supplemented by microscopic examination, had been more reliable, and had given more satisfactory results in water examination than bacteriology. As an aid in forming an opinion, bacteriological investigation was occasionally valuable, but the information it gave never amounted to anything more than mere confirmatory evidence. In the Maidstone investigation, in those cases where Dr. Washbourn had been able to make a positive statement, Dr. Adams would have been able to speak most positively, and no doubt did so, even from the yield of albuminoid ammonia alone; and, of course, when the nitrates also were considered, there was unquestionable, and, indeed, crushing, evidence in support of the position which Dr. Adams had taken up. There was no doubt that the detection of a large number of coli bacilli, or the detection of a large number of bacteria of any kind over and above what was normally found in a given supply, afforded valuable confirmatory evidence; but that was all, up to the present, that bacteriology had been able to do. He should like to point out that for a considerable period Dr. Adams had examined the water of his district. By this examination he was enabled to obtain what he described as his local standard, and was thereby able to gauge with accuracy any change that might take place in the character of the supply; but on the ground of so-called economy the local authority decided to dispense with this measure of precaution. They and the population they were supposed to represent had been punished most severely for that action, and the lesson was one which ought not to be forgotten.

Mr. F. WALLIS STODDART said he had been reluctantly forced to the conclusion that the detection of the typhoid bacillus under the usual circumstances of an epidemic was impracticable. He would go even further, and say that he did not think it ought to be undertaken, except as a piece of scientific research. It was desirable that something like a definition of *Bacillus coli communis* should be formulated. He had obtained pure cultures from the original discoverer, Escherich, but the organism obtained from these pure cultures was quite different from anything that had been obtained by himself, or by any of his bacteriological friends, and as long as that state of affairs existed, he felt some diffidence in saying that any organism was *Bacillus coli*, or that it was derived from intestinal sources. He was obliged to

support Mr. Hehner and Mr. Cassal in saying that unquestionably, as a guide to the quality of ground waters, there was nothing to compare with chemical analysis judiciously applied. He thought the relation of nitrates to the organic matter of sewage, both dead and living, was, perhaps, scarcely appreciated. The formation of nitrates was the outcome of a series of fermentations of dead organic matter, and it had been experimentally demonstrated that the process of nitrification could be carried out to completion without apparently interfering with the vitality of any pathogenic organisms that might be present. He gathered that Dr. Adams shared the current opinion that water falling on the surface of the ground actually sank uniformly, so to speak, through the soil, and underwent a gradual process of filtration, which resulted, first, in the elimination of these organisms; secondly, in the production of nitric acid; and ultimately in the complete purification of the water. This, however, he thought was not the case. The water travelled, and was to be obtained in quantity, only in natural passages, either between impervious strata or through fissures in those strata. Even in the case of such a pervious medium as the chalk, the water did not pass uniformly through in bulk. It invariably found the easiest channel to flow through, and nitrification was all the more complete as the water became more completely aërated during its flow. The very openness of the channel would permit the organisms to travel through a considerable thickness of subsoil. From these considerations he thought it quite possible that a water like many of these samples might be quite devoid of chemically demonstrable organic matter, and yet contain pathogenic organisms in an active and vigorous condition.

Dr. VOELCKER, while agreeing as to the desirability of local standards, said that it appeared to him to be a not very easy thing to fix a proper local standard. If the standard taken was that of a doubtful source, wrong conclusions would necessarily be formed. The real difficulty was to know whether the local standards adopted were really representative ones or not. Mr. Cassal had remarked that some of Dr. Adams' samples might have been condemned on account of the albuminoid ammonia alone. He (Dr. Voelcker) would have been very sorry to do that in any case without knowing absolutely the nature of the supply. Nor could he altogether subscribe to Dr. Adams's theory of zones. The nature of the soil seemed to have been left very much out of account. It would hardly be possible to divide all soils up into zones, and to assume that a certain set of operations went on in one zone and not in another, independently of the nature of the soil.

Dr. ADAMS, referring to Dr. Washbourn's remarks with reference to the probable cause of the premonitory diarrhœa that had occurred, observed that this diarrhœa occurred at the very commencement of the epidemic, and before the typhoid really set in, and ceased absolutely immediately the typhoid began. The two disorders must be totally and entirely different. The one exhibited as clearly as possible the characteristics of a chemical poisoning, and the other those of a bacterial poisoning. The typhoid continued to spread over a considerable time, as long, in fact, as the water containing the organisms was allowed to be drunk; the diarrhœa, on the other hand, without any interposition, occurred at the commencement of August, and concluded practically within that month, whereas the water which was believed to have been the cause was being freely drunk until the 26th or 28th of the following

month. What he maintained was, that during the whole of the dry season the putrefactive changes in the animal organic matter were going on, and that these changes brought with them certain chemical results, which accumulated on the surface, and which, being soluble, were at once carried into the water when the rain fell, and were thus consumed. Their effect then ceased, because there was no continuance of the causes which produced, and therefore no reproduction of the poisonous material. If the diarrhœa had been caused by bacteria, which simply differed from the typhoid organism in having a shorter incubation period, it might reasonably have been expected that such diarrhœa organisms would multiply and continue their effect in like manner with the typhoid organisms; but that was not so: the diarrhœa began and was ended before the typhoid started. With regard to Mr. Stoddart's observations, he of course had in view the question of local circumstances, which must be taken into consideration in the selection of local standards; though he might remark that all the waters to which he had referred in the paper came from soils which, for all practical purposes, might be regarded as precisely similar.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Detection of Citric Acid in Vegetable Juices, Wine, and Milk. G. Deniges. (*Rev. Chim. Analyt. appl.*, vol. vi. [7], pp. 110-112.)—The method is based on the fact that under the influence of manganic oxidizing agents, and in an acid medium, citric acid forms with mercury a compound insoluble in presence of mercuric sulphate. It is applied as follows:

(*a*) *Free or Combined Citric Acid in Aqueous Solution.*—Five c.c. of a 1 to 2 per cent. citric acid solution are heated to boiling along with 1 c.c. of mercuric sulphate —prepared from mercuric oxide, 5 grammes; concentrated sulphuric acid, 20 c.c.; water, 100 c.c.—and, on removing from the flame, are treated with 5 to 6 drops of a 2 per cent. solution of potassium permanganate—or 1 drop if the liquid be very dilute —which decolorizes the liquid and throws down a white precipitate. This test will reveal the presence of 0·5 milligramme of citric acid.

(*b*) *In Vegetable Juices.*—A few drops of the juice are diluted with 4 to 5 c.c. of water and tested as above.

(*c*) *Small Quantities of Citric Acid in Presence of a Large Amount of Tartaric Acid.* —Five c.c. of a 2 per cent. solution of the average sample are heated with 1 c.c. of 2 per cent. permanganate until the mixture acquires a brown tinge and disengages a few bubbles of gas. When decoloration has set in, 1 c.c. of mercuric sulphate solution is added, and the whole is again heated to boiling. A decided white turbidity is obtained in presence of less than ½ per cent. of citric acid.

(*d*) *In Wine.*—Ten c.c. of wine are well shaken up with 1 to 1½ grammes of lead

dioxide, followed by 2 c.c. of mercuric sulphate solution. After filtration, 5 to 6 c.c. are heated to boiling and treated with 1 drop of permanganate, 9 additional drops being added in succession as decolorization ensues.

Under this treatment normal wines give merely a very slight haze, not always appearing at once, due to the traces (5 to 6 centigrammes per litre) of citric acid invariably present, a fact not hitherto recorded. With 0·1 gramme per litre the turbidity is pronounced, and above 0·4 gramme a flocculent precipitate is formed.

(*e*) *In Milk.*—Ten c.c. of milk, 2 c.c. of a 5 per cent. solution of sodium metaphosphate, and 3 c.c. of the above mercuric reagent, are shaken up together and filtered, the first runnings being rejected, 5 to 6 c.c. heated to boiling and shaken up with successive drops of the permanganate solution. A decided white turbidity ensues after the addition of 4 or 5 drops in the case of cows' milk, and with 8 to 10 drops a flocculent white precipitate accompanied by a yellow coloration, removable by hydrogen peroxide.

The author has ascertained that acetic, tartaric (etc.) acids, glycerin, gum, and other substances likely to occur with citric acid, do not interfere with the reaction; any excess, however, of chlorides, bromides, or iodides, must be first eliminated by silver sulphate. When oxalic acid or other substance capable of reacting on mercuric sulphate is present, the mixture must be first oxidized in an acetic medium by a slight excess of permanganate, which is then reduced by hydrogen peroxide before proceeding to apply the test. C. S.

Adulteration of Pimento. T. F. Hanausek. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 245.)—The author calls attention to the adulteration of pimento with roasted cacao husks. The adulteration may be known by the presence of homogeneous acute-angled particles of a reddish-brown colour bordered by dark brown on one side or on two opposite sides. Treatment with hot water or solution of potash yields a slimy membrane, and particles may be seen composed of a spongy tissue with sclerogen. Adhering to particles of spongy parenchyma are bundles of spires. These also occur separately, and contain spiral fibres, often in the form of open rings. H. H. B. S.

Determination of Oil of Mustard. E. Haselhoff. (*Zeit. fur Untersuch. der Nahr. und Genussmittel*, 1898, 235.)—The methods for the determination of oil of mustard depend upon the estimation of the sulphur or nitrogen contained in it.

Förster (*Landw. Versuchs. Stat.*, xxxv., 209) converts the oil into thiosinamin, and precipitates the sulphur with mercuric oxide as mercuric sulphide.

Schlicht (*Zeit. anal. Chemie*, xxx., 661) distils with an alkaline solution of potassium permanganate, reduces the excess of permanganate with alcohol, and determines the sulphuric acid by barium chloride.

Passon (*Zeit. angw. Chemie*, 1896, 422) determines the nitrogen by Kjeldahl's method.

The author has made a comparative examination of these three methods as well

as of a modification of Schlicht's method, consisting in the use of bromine-water in place of potassium permanganate. The mean results are given in the following table:

Amount present.	Found by Förster's Method.	Found by Schlicht's Method.		Found by Passon's Method.
		Permanganate.	Bromine.	
.96·72	95·34	95·44	96·47	95·44

According to Schuster and Mecke (*Chem. Zeit.*, xvi., 1954), the rise in temperature which takes place on milling rape-seed prior to pressing out the oil increases the percentage of oil of mustard in the seed threefold. The author's experiments do not confirm this. In the following case a small increase resulted on heating to 70° C., but by no means to the extent mentioned by Schuster and Mecke:

Fresh rape-seed	0·305	per cent.	oil of	mustard.
Defatted rape-seed	0·290	,,	,,	,,
Rape-seed heated to 70° C	0·347	,,	,,	,,

H. H. B. S.

INORGANIC ANALYSIS.

Volumetric Determination of Antimony. G. Rollin. (*Rev. de Chim. et de Pharm.*, 1898, February 10, p. 129; through *Rev. Chim. Analyt. appl.*, vol. vi. [7], pp. 114, 115.)—The author bases his method, which is applicable to the sulphides and commercial oxides of the metal, on the following considerations:

1. The Mohr titration is accurate provided the solution is kept alkaline by means of a bicarbonate throughout the operation.

2. Arsenic sulphide is completely insoluble, whereas the antimony salt is soluble in *cold* concentrated hydrochloric acid, and so long as the substance does not contain more than 5 parts of arsenic oxide per 100 of antimony oxide, the precipitate produced under these conditions is free from the latter metal.

3. A current of air has no action on cold solutions of antimony chloride.

4. A solution of antimony in a large excess of hydrochloric acid may be boiled for a long time without loss of metal.

In testing commercial oxides of antimony, 1 gramme of substance is dissolved in 10 c.c. of hydrochloric acid of a specific gravity of 1·176, and treated with gaseous sulphuretted hydrogen to remove arsenic. The liquid being then transferred to a 250 c.c. flask and the glass rinsed with a little hydrochloric acid diluted with its own bulk of water (not more), the excess of sulphuretted hydrogen is removed by a current of air. Five grammes of tartaric acid are added, the liquid made up to the mark, and passed through a dry filter. One-tenth of this volume is taken for titration, carefully saturated with sodium bicarbonate solution, and, after adding a pinch of the solid salt and a little starch paste, is titrated with standardized iodine solution.

In the case of antimony sulphide, 1·5 grammes are dissolved in hot concentrated

hydrochloric acid, and, when *perfectly cold*, treated by sulphuretted hydrogen, etc., as before. C. S.

Separation of Thorium from Cerite Earths. Wyrouboff and Verneuil. (*Comptes rendus*, vol. cxxvi., p. 340; through *Rev. Chim. Analyt. appl.*, vol. vi. [7], pp. 112, 113.)—The method is based on the transformation of thoria into peroxide by means of hydrogen peroxide (proposed by Clève). The substance is dissolved in nitric acid, and a quantity of the solution corresponding to 0·5 gramme (maximum) of the oxides is evaporated to dryness, and treated with 100 c.c. of water and an equal quantity of hydrogen peroxide, the whole being heated and stirred for several minutes. The bulky gelatinous precipitate is washed until the washings no longer give a precipitate with ammonia, and, after removal from the filter, is redissolved in a little hot water containing 2 grammes of ammonium iodide and 2 c.c. of concentrated hydrochloric acid, the hot solution being passed through the filter to dissolve any residual peroxide thereon. The hydroxide thrown down by ammonia is thrown on the same filter and calcined without washing, the filtrate being treated with ammonia to precipitate the other earths present in the substance.

If the precipitate produced by hydrogen peroxide is not perfectly white, it contains cerium, and should be purified by re-solution in nitric acid and treating as before—a course advisable in any case, to ensure at the same time the total precipitation of the thorium present. C. S.

Differentiation of Alkali Bicarbonates and Carbonates in Mixtures. A. Leys. (*Ann. Chim. Analyt.*, vol. iii. [2], pp. 44-46.)—The precipitation of neutral alkali carbonates by magnesium salts being masked by the solvent action of an alkali bicarbonate or of borax in mixtures, the author has studied the reaction of the calcium salts in this connection, and finds that by using a saturated solution of calcium sulphate the neutral carbonates are thrown down immediately as an opaque white precipitate, whilst precipitation of the bicarbonates occurs only after prolonged contact with this precipitate. The crystalline powder, which then separates out, is readily distinguishable from the former. Thus, in the case of "pure" commercial sodium bicarbonate, if a quantity of water insufficient for complete solution be added, and a portion of the solution dropped into the reagent, an opaque precipitate indicating neutral carbonate is obtained. C. S.

Separation and Estimation of Iodine, Bromine, and Chlorine. A. Carnot. (*Comptes rendus*, vol. cxxvi. [3], p. 187; through *Rev. Chim. Analyt. appl.*, vol. vi. [3], pp. 34-36.)

Iodine.—The neutral solution of chlorides, bromides, and iodides is diluted to 200 c.c. and placed in a stoppered 400 c.c. flask, terminating below in a narrow tapped tube. Here the iodine is liberated by means of 10 drops of sulphuric acid saturated with nitrous fumes, and extracted by shaking the liquid up with 10 to 15 c.c. of carbon disulphide, which, on settling, is drawn off through the tap.

This operation is repeated twice, and on the last occasion the solvent should remain colorless. The carbon disulphide is placed on a moistened filter and the first washings are returned to the original liquid, the disulphide being then run through the perforated filter into a flask, where it is mixed with 30 c.c. of a ½ per cent. solution of sodium bicarbonate and titrated with standard sodium thiosulphate.

Bromine.—Several c.c. of 10 per cent. chromic acid and 3 to 4 c.c. of sulphuric acid diluted with its own volume of water are added to the liquid separated from the iodine, and the closed flask is placed in a boiling-water bath for an hour. The bromine is then extracted from the cooled liquid by carbon disulphide as in the case of the iodine, the disulphide solution being well shaken up with a little potassium iodide and 30 c.c. of ½ per cent. sodium bicarbonate, and the liberated iodine titrated with sodium thiosulphate; the bromine is found by multiplying the weight of iodine by 0·6308.

Chlorine.—The residual acid solution is diluted to 500 c.c., and warmed gently along with silver nitrate to cause the precipitate to collect. The latter is purified from the silver chromate usually present by treatment with hot water slightly acidified with nitric acid, and is finally washed, dried, and weighed. C. S.

Determination of the Strength of Hydrofluoric Acid Solutions. J. Zellner. (*Monatsheft. für Chemie*, xviii., 749.)—A volumetric process is recommended, consisting of titration by potash, using phenolphthalein as the indicator. A moderate excess of alkali is added, the solution boiled for a short time, and titrated back while hot. Comparative tests made volumetrically, in this way, and afterwards in the same portion gravimetrically, gave the following results, in parts per cent.:

	I.	II.	III.	IV.
By volumetric method	5·22	7·63	21·27	31·40
By gravimetric method	5·20	7·68	21·56	31·65

If the titration is carried out in the cold, the results, though agreeing between themselves, are about 1 per cent. below the gravimetric tests. For weighing the quantity of hydrofluoric acid taken for the determination, a cylindrical vessel of hard indiarubber is used, having an outlet at the bottom through a flexible small bore caoutchouc tube provided with a pinchcock. The apparatus, which weighs about 60 grammes, can be secured to the pan of the balance by a piece of platinum wire. It is first weighed full, and then after running out the required quantity of acid, the weight taken being obtained by difference. H. H. B. S.

The Determination of Boric Acid as Potassium Borofluoride. K. Thaddéeff. (*Zeit. anal. Chem.*, 1897, xxxvi., 568-637.)—After giving a summary of the various methods employed for the determination of boric acid, and showing the unreliability of any of those based on an estimation by difference, the author describes a modification of the Berzelius-Stromeyer method which he considers highly satisfactory when carried out exactly as described below. When in combination with a base, except potassium, the boric acid is distilled over with sulphuric acid and methyl alcohol, as in Rosenbladt's apparatus, a regulated air-current being at the same time introduced into the distilling flask. The distillate from the substance containing

1 gramme or less of boric acid is received in a platinum basin containing a 10 per cent. solution of pure caustic potash, and when four successive quantities of 10 c.c. of methyl alcohol have been distilled over, is concentrated to half its volume on the water-bath. An excess of pure hydrofluoric acid is then added, and the evaporation continued until only a faint smell of hydrofluoric acid is perceptible. When cool, 50 c.c. of a solution of potassium acetate (specific gravity 1·14) are added, and the basin is allowed to stand for one or two hours at the ordinary temperature, the mass being frequently stirred with a platinum rod so as to ensure the whole of the potassium hydrogen fluoride dissolving. 100 c.c. of alcohol (specific gravity 0·805) are next added, the liquid carefully stirred and allowed to remain over-night.

Meanwhile, a filter-paper has been prepared (a No. 590 Schleicher and Schüll, 9 c.m. in diameter), moistened with alcohol, dried at 100° to 110° C., and weighed in a stoppered weighing-flask. The insoluble residue of potassium borofluoride is washed on to this filter with alcohol of 0·805 specific gravity, and the washing continued until on evaporating a few drops of the filtrate on platinum foil, no more residue remains than the small amount of borofluoride soluble in the alcohol (0·000014 gramme per c.c.). From 62 to 72 c.c. of alcohol are usually required. The filter and precipitate are then dried at 100° to 110° C. for three hours, and weighed. The following are some of the results obtained in this way with borax:

Borax taken. Grammes.	KBF_4. Grammes.	B_2O_3 formed. Grammes.	Per cent.	Difference from theory. Per cent.
1	1·3229	0·3653	36·53	−0·06
0·5	0·6631	0·1831	36·62	+0·03
0·1	0·1308	0·0361	36·12	−0·47

C. A. M.

The Commercial Analysis of Bauxite. W. B. Phillips and D. Hancock. (*Jour. Amer. Chem. Soc.*, 1898, xx., 209-225.)—The author states that the formula given by Roscoe for bauxite, $(AlFe)_2O(OH)_4$, does not apply to the American mineral, which consists essentially of a mixture of aluminium trihydrate with clay and another aluminium compound, possibly a lower hydrate.

In assaying the material for alum manufacture it is usual to evaporate it with sulphuric acid until the latter begins to fume; but in this way aluminium compounds are brought into solution which are not very suitable for the manufacture, and are certainly of very much less value than the readily soluble trihydrate. The author therefore recommends that the alumina soluble during one hour in sulphuric acid of a specific gravity of 1·516, at 100° C. shall be described as "free alumina," and that soluble on evaporating the acid to fumes as "available alumina," whilst the difference between the two shall be known as "combined alumina." He describes experiments which prove that practically the whole of the aluminium trihydrate is dissolved by the first treatment, and that concordant results can be obtained.

The analytical method recommended is as follows: The sample is finely powdered and passed through a sieve of 100 meshes to the inch.

Moisture.—Two grammes are dried to constant weight at 100° C.

Available Alumina.—Two grammes of the bauxite are mixed with 10 c.c. of cold

sulphuric acid (S.G. 1·516), and the basin gradually heated until fumes begin to appear. It is then covered with a glass, and the heating continued for ten minutes. When cool, 100 c.c. of hot water are added, and after being boiled for five minutes the liquid is filtered, the residue washed, and the filtrate and washings made up to 200 c.c.

Fifty c.c. are diluted to 300 c.c., 2 c.c. of hydrochloric acid added, the liquid boiled, ammonia added in slight excess, and the boiling continued for five minutes. The precipitate is filtered off, washed, dried, ignited, and weighed as alumina, ferric oxide, and titanium dioxide, and the two latter are separately determined and deducted.

Estimation of Titanium Dioxide.—To 50 c.c. of the main solution, ammonia is added until there is a slight precipitate. This is just dissolved in sulphuric acid, and the liquid is made up to 350 to 400 c.c. and boiled for an hour. Any iron present is reduced by means of sulphur dioxide, care being taken that the liquid smells of the gas during the boiling. In this way the titanium dioxide is precipitated practically free from iron. The precipitate is filtered while hot through a double filter, washed with hot water, dried, ignited, and weighed.

Estimation of Ferric Oxide.—This is determined in the filtrate from the titanium dioxide by reduction with zinc and titration with permanganate.

Estimation of "Free Alumina."—Two grammes of bauxite are mixed with 10 c.c. of sulphuric acid (S.G. 1·516) in a 4-oz. Erlenmeyer flask, which is provided with a perforated stopper. The flask is heated on the water-bath at 95° to 100° C, with frequent shaking for an hour, after which 100 c.c. of hot water are added and the flask kept in the water for ten minutes. The liquid is filtered, the residue washed with hot water, and the alumina determined in the filtrate as before, with the exception that the titanium dioxide, which is not dissolved under these conditions, is not determined. The precipitate consists of alumina and ferric oxide, and the latter is separately determined in the usual way and deducted.

Combined Alumina is the difference between the available alumina and the free alumina.

In order to determine the silica and the total alumina, etc., the insoluble residue left on treating the mineral with the sulphuric acid may be ignited with the filter-paper, the ash fused with potassium bisulphate, and the melt left in cold water containing at least 5 per cent. of sulphuric acid until decomposed. The silica is filtered off, ignited, and weighed, and the alumina, ferric oxide, and titanium dioxide determined in the filtrate, and added to the amounts found in the determination of the available alumina.

It is not advisable to determine the silica in the insoluble residue by treatment with hydrofluoric acid, since some of the titanium dioxide is simultaneously volatilized.

C. A. M.

NOTE.—It is well known that if sulphuric acid, as well as hydrofluoric, is employed in the elimination, the titanium dioxide is completely retained.—B. B.

Analysis of Calcium Carbide. H. Bamberger. (*Zeit. angew. Chem.*, 1898, 196-198.)—In place of the ordinary methods of determining volumetrically the amount of acetylene obtainable from a given weight of carbide, which have the draw-

back that a correction must be made for the gas absorbed by the liquids with which it comes in contact, as well as the ordinary corrections for temperature and pressure, the author prefers to use a gravimetric method; the principle of which is the same as that for the determination of carbonic acid in carbonates by difference.

C. A. M.

On the Products of the Decomposition of Calcium Carbide by Water. E. Chuard. (*Bull. Soc. Chim.*, 1897, xvii., 678, 679.)—The author has established the presence of ammonia not only in the acetylene liberated from the carbide, but also in the residue. For 100 parts of calcium carbide the gas contains from 0·03 to 0·06 of ammonia, the residue 0·24 to 0·40. The ammonia liberated with the acetylene is derived from the decomposition of calcium nitride, $Ca_3N_2 + 3H_2O = 3CaO + 2NH_3$, whilst that in the residue is a product of the decomposition of calcium cyanate :—

$$Ca(CNO)_2 + 3H_2O = CaCO_3 + CO_2 + 2NH_3.$$

Other impurities invariably present are phosphoretted and sulphuretted hydrogen. It is to the presence of the former, the amount of which is usually 0·018 to 0·032 per cent. on the carbide, that the insecticidal properties of crude acetylene are probably due.

C. A. M.

LEGAL.

QUEEN'S BENCH DIVISION.

COURT FOR THE CONSIDERATION OF CROWN CASES RESERVED.

Reprinted from the "Times" of May 2, 1898.

(Before the LORD CHIEF JUSTICE OF ENGLAND, MR. JUSTICE DAY, MR. JUSTICE WILLS, MR. JUSTICE GRANTHAM, MR. JUSTICE WRIGHT, MR. JUSTICE KENNEDY and MR. JUSTICE CHANNELL).

PETCHLEY *v.* TAYLOR.

THIS was a case stated by a Metropolitan police magistrate upon convicting the appellant upon an information preferred under the Sale of Food and Drugs Act, 1875, for unlawfully selling to the prejudice of the purchaser milk which had 97 per cent. of the original fat abstracted, so as to affect injuriously its quality and substance, without making disclosure of the said alteration, contrary to Section 9 of the above Act.

Mr. George Elliott appeared for the appellant; and Mr. Courthope Munroe for the respondent.

On November 13, 1897, the appellant sold to the respondent a tin containing a substance described as "Cup Brand Condensed Milk." On the tin were the words, "This tin contains skimmed milk with nothing added but the finest sugar." The substance in the tin was proved to be separated milk, or milk from which the cream had been separated by means of a machine called a separator, and that 97 per cent. of the original fat had been abstracted. It was also proved that the term "skimmed milk" meant milk from which a portion of the fat had been removed by the process of skimming the surface of the milk, and that the greatest amount of fat that could be thus removed was 63 per cent.

Mr. Elliott contended that the alteration was sufficiently disclosed by the term "skimmed milk," and cited "Jones *v.* Davies" (69 L.T., 497) and "Platt *v.* Tyler" (58 J.P., 72).

The Court yesterday dismissed the appeal.

THE ANALYST.

JULY, 1898.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, June 1, in the Chemical Society's Rooms, Burlington House, the President (Dr. Bernard Dyer) occupying the chair.

The minutes of the previous meeting were read and confirmed.

Mr. H. J. Lewin was elected a member, and Mr. F. M. Wharton an associate of the Society.

Mr. G. W. Slatter, A.R.C.S., F.I.C., was proposed for election as a member, and Mr. A. J. Bull, assistant to Mr. Chattaway, was proposed for election as an associate.

The PRESIDENT, referring to the recent death of Lord Playfair, who had been an honorary member of the Society almost from the beginning of its history, moved from the chair that a message of condolence be forwarded to Lady Playfair by the Society. The motion was carried unanimously.

The following papers were read:

"Note on some Apparatus." By H. Droop Richmond.

"Sewage Analysis and Standards of Purity for Effluents." By C. G. Moor, M.A.

"Note on Certain Resins." By Rowland Williams.

"The Proportion of Oxygen Present in Linseed-Oil, both before and after Oxidation." By Rowland Williams.

"Variations in the Composition of Chicory." By Bernard Dyer, D.Sc.

"The Sulphuric Acid in Portland Cement." By Eug. Ackermann.

THE CALCULATION OF "ADDED WATER" IN ADULTERATED MILKS.

By H. DROOP RICHMOND.

(*Read at the Meeting, March* 16, 1898.)

IF we add to or take from a milk any quantity of fat, we shall not affect the percentage of solids-not-fat in the "milk devoid of fat."

Calling the solids-not-fat S, and the fat F, the following equation holds true for any given milk, and the cream and skim milk prepared from it:

$$\frac{S}{100-F} \times 100 = K_1 \ldots\ldots\ldots (1).$$

K_1 represents the percentage of solids-not-fat in the "milk devoid of fat."

I have already shown that the following equation connects total solids, fat, and specific gravity (ANALYST, xix., 81):

$$T = 0{\cdot}2625\,\frac{G}{D} + 1{\cdot}2\,F \ldots\ldots (2);$$

where T = total solids;
G = degrees of gravity (water at 60° = 1000);
D = density (water at 60° = 1);
F = Fat.

[D and G are different modes of expression of the same fact; the expression $\frac{G}{D}$ can be expressed either in terms of G, as $\frac{1000\,G}{1000+G}$, or in terms of D, as $\frac{1000\,D-1000}{D}$; the expression $\frac{G}{D}$ is adopted as being less cumbersome. It really represents "degrees of specific volume."]

I have also shown (ANALYST, xx., 57) that equation (2) may be written:

$$T = 0{\cdot}25\,G + 1{\cdot}2\,F + 0{\cdot}14 \ldots\ldots (3).$$

The difference between the results given by equations (2) and (3) does not exceed 0·02 per cent.

It is evident that as the total solids are composed of fat and solids-not-fat, we can substitute F + S for T in equation (3), which is then written:

$$F + S = 0{\cdot}25\,G + 1{\cdot}2\,F + 0{\cdot}14,$$

or,
$$S = 0{\cdot}25\,G + 0{\cdot}2\,F + 0{\cdot}14 \ldots\ldots (4).$$

We may substitute for S in equation (1) the value given by equation (4):

$$\frac{0{\cdot}25\,G + 0{\cdot}2\,F + 0{\cdot}14}{100 - F} \times 100 = K_1.$$

This may be written:

$$\frac{0{\cdot}25\,G + 0{\cdot}25\,F + 0{\cdot}14 - {\cdot}05\,F}{100 - F} \times 100 = K_1;$$

or,
$$0{\cdot}25\,G + 0{\cdot}25\,F + 0{\cdot}14 - 0{\cdot}05\,F = K_1 \times \frac{100 - F}{100};$$

or,
$$0{\cdot}25\,G + 0{\cdot}25\,F = K_1 \times \frac{100 - F}{100} - 0{\cdot}14 + 0{\cdot}05\,F;$$

or,
$$G + F = 4 \times K_1 \times \frac{100 - F}{100} - 0{\cdot}56 + 0{\cdot}20\,F;$$

or,
$$G + F = 4 \times K_1 - 0{\cdot}56 + 0{\cdot}20\,F - \frac{4 \times K_1}{100} \times F \ldots\ldots (5).$$

The average value of K_1, the percentage of solids-not-fat in the "milk devoid of fat," is about 9·0, and the value of $\frac{4 \times K_1}{100}$ may be taken as 0·36.

Equation (5) may be written:

$$G + F = 4 \times K_1 - 0{\cdot}56 + 0{\cdot}20\,F - 0{\cdot}36\,F;$$

or,
$$G + F = 4 \times K_1 - 0{\cdot}56 - 0{\cdot}16\,F \ldots\ldots (6).$$

For comparatively small values of F the expression $(-0{\cdot}56 - 0{\cdot}16\,F)$ will approximate to a constant, and equation (6) becomes:

$$G + F = \text{constant} \ldots\ldots (7).$$

In the following table I have given a series of analyses of milks which were known to be not watered; the samples connected by brackets were identical, but the analyses were performed by different analysts working independently:

G.	T. S.	F.	S.-not-F.	G+F.
32·0	12·55	3·79	8·76	35·79
31·8	12·44	3·70	8·74	35·50
31·2	12·27	3·65	8·62	34·85
31·9	12·38	3·67	8·71	35·57
31·8	12·24	3·50	8·74	35·30
31·2	12·09	3·58	8·51	34·78
31·2	12·36	3·80	8·56	35·00
30·2	12·38	4·08	8·30*	34·28
30·7	12·56	4·10	8·46	34·76

	Total mean		8·88	36·02

In these it is seen that the maximum difference between two analysts is 0·30 per cent. of solids-not-fat, or 3·3 per cent. of the mean; the maximum difference between the sums of the gravity and the fat found by two analysts is 0·78, or 2·2 per cent. of the mean. The extreme differences (excluding the separated milks) in the table amount to 1·04 per cent. solids-not-fat, or 11·7 per cent. of the mean; and of the sums of gravity and fat to 3·32, or 9·2 per cent. of the mean. It appears that the sum of the gravity and fat is not only less affected by experimental error than the solids-not-fat, but that it is a more constant figure in genuine milks.

In the following table, series of analyses of the same milk in which the fat has been varied, are given:

No.	Specific Gravity.	Total Solids.	Fat.	Solids-not-Fat.	Sum.	Deviation from Mean.
I.	1·0327	11·62	2·75	8·87	35·45	−0·10

VI.	1·0318	11·89	3·17	8·72	34·97	+0·01
	1·0312	12·45	3·75	8·70	34·95	−0·01
VII.	1·0313	12·95	4·10	8·85	35·40	−0·08
	1·0262	17·92	9·36	8·56	35·56	+0·08

It is seen from this series that the sum of the gravity and fat remains appreciably constant when considerable variations occur in the fat; the difference, except in No. V., is not greater than the divergence between the results of two analysts working independently on identical samples; No. V. is included to show the maximum difference yet observed. The table could be greatly extended, but the results given above are sufficient.

I venture to propose, therefore, that the sum of the fat and gravity be used for the calculation of added water instead of the solids-not-fat, because—

(i.) It is less affected by experimental error;

(ii.) It is a more constant figure;

(iii.) It is but slightly affected by excess or deficiency of cream.

The value 36·0 may be taken as the mean, and should be used where a mean percentage of added water is desired. From the above table, it appears that the value 34·5 may be used where a safe percentage of added water is to be certified, in the same way that the standard of 8·5 per cent. solids-not-fat is used.

In the following table some analyses of watered milks are given; the percentage of added water is calculated from the solids-not-fat using 8·88 (the mean value found above) as a standard, and from the sum of the fat and gravity using 36·0 (the mean given above):

No.	Specific Gravity.	Total Solids.	Fat.	Solids-not-Fat.	Sum.	Added Water. From Solids-not-Fat.	Added Water. From Sum.	Added Water. Actual.
1*a*.	1·0295	11·31	3·08	8·23	32·58	7·3	9·5	10

8.	1·0290	11·66	3·55	8·11	32·55	8·7	9·6	10·5
9.	1·0293	11·32	3·20	8·12	32·50	8·6	9·7	7·5

The analyses 1*a*, 1*b* and 1*c*, 2*a* and 2*b*, and 3*a* and 3*b*, were made by different analysts working on identical samples. No. 1 was milk which had been watered; No. 2 had also received an addition of cream; while No. 3 contained a proportion (30 per cent.) of separated milk. The percentages of water calculated by the method above described agree better with that actually added than the percentages deduced from the solids-not-fat.

It is not claimed that a determination of fat and specific gravity can supplant in any way estimations of total solids, solids-not-fat, milk-sugar, proteids, and ash, in judging whether a milk is genuine or not; but determinations of specific gravity and fat are always made in an ordinary analysis. It appears from the above evidence that, when watering is established by the ordinary analytical methods, a more correct estimate of the percentage of water added can usually be obtained by

calculating from the sum of specific gravity and fat; and the calculation is of the very simplest.

In this paper I have made use of analyses by Messrs. Bevan, Boseley, Harland, Hehner, and O'Shaughnessy, as well as my own, and my best thanks are due to these gentlemen for permission to use their work.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

The Detection of Annatto in Milk. A. Leys. (*Journ. Pharm. Chem.*, 1898, vii., 286-289.)—Fifty c.c. of the suspected milk are shaken in a separatory funnel with 100 c.c. of the following mixture made in the following proportions: Alcohol (93 per cent.), 240 c.c.; ether, 320 c.c.; water, 20 c.c.; ammonia solution (specific gravity 0·92), 8 c.c. On standing, the liquid forms two layers, the upper consisting of an ethereal solution of the fat, and the lower containing the casein, etc. The coloring matter of annatto will be found almost entirely in this lower ammoniacal layer, to which it imparts a greenish-yellow tint.

After twenty minutes the lower layer is removed to a second separatory funnel, and half its volume of a 10 per cent. solution of sodium sulphate added to it in small fractions, the funnel being inverted without shaking after each addition. The casein is thus separated in flakes, which conglomerate and rise to the surface, and the liquid is drawn off from below through wire gauze and placed in four test-tubes. To each of these amyl alcohol is added, and after shaking they are placed in a vessel of cold water, and the temperature gradually raised to 80° C., which causes the emulsion to break up, and the amyl alcohol, with the coloring matter in solution, to rise to the surface.

The residue obtained on evaporating the united amyl alcohol extracts is dissolved in warm water containing a little ammonia and alcohol. A bundle of white cotton fibre is introduced, and the solution evaporated almost to dryness on the water-bath. The yellow fibre, when washed and placed in a solution of citric or other weak acid, is instantly changed to a rose colour when the milk had been colored with annatto.

An uncoloured milk when tested in this way gives a slight yellow coloration to the cotton, but never the rose colour. Similarly negative results are obtained in the case of milk colored with saffron, turmeric, or with the coloring matter of marigold flowers, so that the reaction appears to be characteristic of annatto. C. A. M.

The Detection of Added Water in Milk. A. Villiers and M. Bertault. (*Bull. Soc. Chim.*, 1898, xix., 305-310.)—The authors state that there exists a peculiar relation between the amount of lactose and of salts in milk-whey, so much so that the refractive power of the latter is virtually a constant. They have established this in the case of thirty-eight samples of milk of undoubted purity, obtained from cows of different breed and age. In these the total solids varied from 110 to 202·4 grammes per litre; those of the whey, after boiling, from 61·20 to 74·60 grammes per litre; the soluble ash from 3·22 to 8·40; lactose from 37·80 to 58·50; and the chlorides, as sodium chloride, from 0·93 to 2·97.

The whey was prepared by adding 1 volume of 1 per cent. acetic acid to 2 volumes of the milk, bringing the mixture to the boiling-point in a flask connected with a reflux condenser, then cooling and filtering.

The total solids were determined by evaporating 5 c.c. in vacuo, and the refractive power by means of Jean and Amagat's oleorefractometer. The latter results were calculated by subtracting from the figure given by the whey diluted with acetic acid, one-third of the difference between the respective figures for the dilute acetic acid and for pure water; deducting from the result the figure corresponding to pure water, and adding to itself one half of the difference.

If, for example, 11·5 divisions were the reading in the case of pure water, 15 divisions that of the dilute acetic acid, and 41 that of the dilute whey, the result corresponding to the substances dissolved in the undiluted whey would be obtained by deducting

$$41 - \frac{15 - 11{\cdot}5}{3} - 11{\cdot}5 = 28{\cdot}3,$$

and adding half the latter number to itself = 42·4. The number of divisions corresponding to the lactose is calculated by multiplying the amount of lactose in 100 c.c. of the milk by 6·17, the number corresponding to 1 gramme of lactose in 100 c.c. Omitting samples containing colostral milk (which are easily recognised by the presence of albumin in the whey prepared in the cold), the lowest result obtained was 39·5, whilst as a rule the figure was 40 to 41. In the case of colostral milk the lowest result was 38·5.

As an example of the application of the method, two samples of genuine milk are mentioned which contained 131·20 and 110·20 grammes of total solids and 58·50 and 45·00 grammes of lactose per litre respectively, so that, even after the addition of 15 per cent. of water, the first would still give superior figures to the second in these particulars. When examined by the oleorefractometer, the first gave a reading of 41 divisions, the second 39·5, whilst the figure obtained on adding 10 per cent. of water to the first was 37.

The second sample was taken from a Dutch cow, and the authors call attention to the importance of the fact that the whey of milk obtained from Dutch cows in general is not marked by a low refractive power, notwithstanding the poorness of such milk, which is often set up as a defence in prosecutions for watered milk.

The subjoined table gives a selection of the results tabulated by the authors :

Origin of Milk.	Age of Cow.	Age of Milk.	Total Solids in Milk.	Total Solids in Whey.	Soluble Ash	Chlorides as NaCl.	Lactose.	Oleorefractometer Readings corresponding to		
								Lactose.	1 Gramme of Substance other than Lactose.	Total Substances dissolved in Whey.

C. A. M.

Analysis of Lemon Syrups. A. Borntraeger. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 225.)—The author communicates the methods he elaborated for the analysis of lemon syrup, and the results obtained.

For the detection of sulphuric, hydrochloric, and boric acids a solution of the sample was evaporated with soda, and the residue charred. One portion of the aqueous extract of the residue was then acidified with hydrochloric acid, and a second portion with nitric acid, and the two portions tested respectively with barium chloride and silver nitrate. A third portion was acidified with hydrochloric acid and tested for boric acid with turmeric paper.

Oxalic acid was tested for by heating an aqueous solution with neutral calcium acetate. For the detection of salicylic acid an aqueous solution was shaken with chloroform, the chloroform removed and filtered repeatedly through dry filter-paper until clear, evaporated, the residue taken up with water, and a dilute solution of ferric chloride added.

The heavy metals were tested for by sulphuretted hydrogen and ammonium sulphide. The total acidity was determined by titration, and from the result that due to tartaric acid was deducted, the remainder being reckoned as citric acid.

The tartaric acid was determined by precipitating as acid potassium tartrate and titrating. To a solution of 20 grammes of the syrup was added 5 grammes of potassium chloride, the solution neutralized with solution of potash and made up to 50 c.c. A solution of 5 grammes of citric acid was then added, the solution stirred, allowed to stand overnight, the precipitated acid potassium tartrate washed, first with

a saturated solution of cream of tartar, and afterwards twice with a 10 per cent. solution of potassium chloride, and finally titrated hot.

For the detection of soluble starch, gum, and dextrin, a moderately strong solution was mixed with six times its bulk of absolute alcohol, the alcohol removed, the residue dissolved in water, and alcohol again added, and the same procedure repeated until the residue contained nothing further of a reducing nature. The residue was then dissolved in water, boiled for fifteen minutes with hydrochloric acid, neutralized and tested with Fehling's solution.

For the detection of gelatin an aqueous solution was tested direct with a solution of tannin. As, however, the presence of much citric acid hinders the precipitation, it is advisable to first neutralize with soda. The presence of an excess of soda, on the other hand, redissolves the precipitate.

For the determination and identification of the sugar, a solution was made by dissolving 5 grammes in 100 c.c. of water. For the determination of the reducing-sugar 25 c.c. of the solution were neutralized with soda and diluted to 100 c.c. Ten c.c. of Fehling's solution and 40 c.c. of water were then added and the titration carried out according to Soxhlet's directions. As the solution of the syrup polarized to the right, and contained no saccharose, the results were reckoned as dextrose. The method used for the detection of saccharose depends upon its inversion by hydrochloric acid. Twenty-five c.c. of the 5 per cent. solution were allowed to stand overnight with 2·5 c.c. of hydrochloric acid of 1·1 specific gravity, the solution neutralized with soda, made up to 100 c.c. and titrated. The polarimeter, however, showed that no reducing sugar had been formed, and therefore no saccharose was present in the sample. Though the 5 per cent. syrup solution showed on the day after its preparation a rotation of +21·9 Ventzke (length of tube = 2 decimetres), only 1·5 per cent. of dextrose anhydride, corresponding to a rotation of +4·9 Ventzke, had been found. This led the author to suspect the presence of very impure starch-sugar containing amylin, which was confirmed in the following way: Ten grammes of the sample were dissolved in water, neutralized while hot with precipitated calcium carbonate, filtered hot, the precipitated calcium citrate with the excess of carbonate washed with boiling water, the filtrate cooled and fermented with must. It was then neutralized while hot, evaporated, treated first with lead acetate and then with sodium sulphate, made up to 100 c.c. and filtered. The liquid showed after four hours as well as after twenty-four hours a rotation of +21 Ventzke = +7° 17′ (2 decimetre tube), whilst its power of reducing was equal to 0·65 gramme dextrose anhydride in 100 c.c., corresponding to +2 Ventzke.

The glycerin was tested for by the German official method for the analysis of dry wines, but none was found.

The author has also made analyses of lemon-juice. The following results were obtained:

H. H. B. S.

The Composition of Semolina and Food Pastes. Balland. (*Journ. Pharm. Chim.*, 1898, vii., 328-330.)—Semolina is prepared from wheat which contains a large proportion of gluten, as, for instance, that grown in Algiers. It is derived from the less starchy part of the grain, and is distinguished from flour by containing more nitrogenous matter (gluten), but less starch, fat, cellulose, and ash. Under the term "food pastes" are grouped such substances as vermicelli, macaroni, and the small fancy shapes such as crosses, letters, etc., used in soup. These consist of semolina kneaded with boiling water. The following table gives the percentage composition of various semolina products used in France, and contains also for the purpose of comparison the analysis of a rice semolina, of tapioca, and of an artificial tapioca manufactured in France from the potato :

	Water.	Nitrogenous Substances.	Fat.	Starch, etc.	Cellulose.	Ash.

C. A. M.

Determination of Tannic Acid in Coffee. H. Trillich and H. Göckel. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 101.)—The authors use the following method: 3 grammes of coffee are boiled four times for half an hour with water, the extracts mixed together and made up to 1,000 c.c. After filtering (linen is first used, and afterwards paper), 400 c.c. of the clear filtrate are taken, and 1 c.c. of solution of basic lead acetate added. The whole is allowed to stand overnight, and is then filtered. The precipitate is washed, decomposed by sulphuretted hydrogen, the excess of this gas boiled off, the solution filtered, the filtrate evaporated, and the residue weighed.

A sample of raw New Granada coffee examined by this method and by Bell's and Krug's methods respectively gave the following results:

	I.	II.	Mean.
By the above method ...	11·86 per cent.	10·88 per cent.	11·37 per cent.
By Bell's method	4·36 ,,	6·25 ,,	5·32 ,,
By Krug's method	11·12 ,,	11·50 ,,	11·31 ,,

The authors find that each time the solution is evaporated to dryness a portion of the tannin becomes insoluble, and therefore evaporation and drying should be avoided until the final stage of the process is reached.

In roasted coffee the greater part of the tannic acid appears to exist in a combined state, and the authors have not succeeded in devising a method for its determination in this case. H. H. B. S.

The Detection of Small Quantities of Cotton-seed Oil in Edible Oils. M. Tortelli and R. Ruggeri. (*Moniteur Scientif.*, 1898, xii., 335-338.)—The authors recommend the following modification of Bechi's test, as being much more sensitive and reliable than the ordinary methods. Five grammes of the oil are saponified with 30 c.c. of an alcoholic solution of potash (60 grammes in 1 litre of 90 per cent. alcohol), and the soap solution neutralized with 10 per cent. acetic acid, and poured in a thin stream into a hot solution of lead acetate (50 c.c. of a 10 per cent. solution with 250 c.c. of water). The resulting lead soap is washed with hot water, dried with filter-paper, and extracted for about twenty minutes with ether under a reflux

condenser. The ethereal solution is transferred to a separatory funnel, shaken with 60 c.c. of 10 per cent. hydrochloric acid, and allowed to stand for some time. The lower layer is run off, the shaking with hydrochloric acid repeated, and the ethereal layer well washed with water, and finally filtered. After evaporation of the ether, the residue of fatty acids is mixed in a test-tube with 10 c.c. of pure alcohol (90 per cent.) and 1 c.c. of a 5 per cent. aqueous solution of silver nitrate, and the tube placed in a water-bath at 70° to 80° C. In the case of pure olive-oil or of olive-oil mixed with other edible oils, but free from cotton-seed-oil, the liquid remains clear and unaltered even after fifteen minutes, or even after several hours. But if as little as 1 per cent. of cotton-seed-oil be present, the reduction commences immediately, and is complete after a few minutes.

The paper contains tables giving the results of the authors' experiments with olive, earthnut, sesame, maize, and colza oils alone, and when mixed with variable proportions of cotton-seed-oil, all of which bear out their statement as to the delicacy of the test. C. A. M.

The supposed Decolorization of Red Wine by Means of Potassium Permanganate. L. Hugounenq. (*Journ. Pharm. Chim.*, 1898, vii., 321-323.) — A sample of white wine examined by the author gave the following analytical results:

Alcohol	7·13 per cent.
Extract (in vacuo)	22·27 per litre.
Ash	3·59
Alkalinity of ash, as potassium carbonate ...	1·16
Potassium sulphate	1·14
Acidity (total), as H_2SO_4	4·25
,, volatile, as $C_2H_4O_2$	1·23
Reducing substances (as glucose)	1·47
Glycerin	1·07

The ash left on incineration was a red, spongy residue, which gave strongly all the reactions for manganese, and on analysis it was found to contain 0·59 gramme as MnO calculated on 1 litre of the wine.

The author's explanation of the presence of so much manganese is that the wine was originally a common red wine, decolorized by means of animal charcoal and potassium permanganate.

For the rapid detection of manganese in such products the following process is recommended: Ten c.c. of the suspected wine are shaken with 1 or 2 c.c. of soda-lye and 1 c.c. of hydrogen peroxide solution. An immediate mahogany brown coloration is obtained with the adulterated wine, whereas in the case of normal white wines only a yellow tint appears when they are subjected to this test. C. A. M.

On the Presence of an Alkaloidal Principle in Natural Wines. G. Guerin. (*Journ. Pharm. Chim.*, 1898, vii., 323, 324.)—In 1868, Oser (*Bull. Soc. Chim.*, x., 295) isolated from the products of the fermentation of sugar by beer-yeast an alkaloid with a composition corresponding to the formula $C_{13}H_{20}N_4$. Its hydrochloride dried

in vacuo formed a hygroscopic white mass, turning brown on exposure to the air. It was suggested that the same alkaloid might be found in wine, beer, etc.

The author has examined a large number of different wines, and in each case has succeeded in obtaining evidence of the presence of an alkaloidal principle, in the following manner: One litre of the wine, after the addition of a crystal of tartaric acid, was evaporated on the water-bath until all the alcohol had been expelled. The liquid was cooled, made slightly alkaline with potassium hydroxide, and extracted with ether. The residue left on allowing the ethereal extract to spontaneously evaporate was dissolved in several drops of water made slightly acid with sulphuric acid, and this solution gave all the general reactions for alkaloids. C. A. M.

ORGANIC ANALYSIS.

Determination of the Solidification-Point of Commercial Paraffin. R. Kissling. (*Chem. Zeit.*, xxii., 209.)—After discussing the official method of the German mineral-oil industry, and comparing it with the usual English method, the author proceeds to describe his own plan for determining the solidification-point of paraffin. The apparatus consists of a glass cylinder 12 centimetres high by 8 centimetres diameter—a beaker with the bottom cracked out answers the purpose—on which rests a cover having a hole in it, of a size to allow a beaker 8 centimetres high by 5 centimetres diameter to pass through and be supported by the rim. The determination is made as follows: 50 grammes of the sample are placed in the beaker, and heated in a water-bath to about 10° above the solidification-point. The beaker is then suspended inside the cylinder, its rim resting upon the cover, and the melted paraffin stirred with a thermometer until a thin layer of solidified paraffin begins to form on the bottom of the beaker. As soon as this point is reached, a skin will be seen to form upon the upper surface, whilst the whole fluid, which until now has remained clear, becomes suddenly flocculent. The temperature is then read off. The beaker should be kept covered during the whole course of the determination, from the melting of the paraffin to the final reading of the temperature. The following results show with what exactness the method can be worked:

		Determinations.			
		1.	2.	3.	4.
Sample	I. ...	54·1° C.	54·0° C.	54·0° C.	54·1° C.
,,	II. ...	54·5° C.	54·5° C.	54·4° C.	54·3° C.
,,	III. ...	53·8° C.	53·7° C.	53·8° C.	53·9° C.
,,	IV. ...	52·0° C.	52·0° C.	52·1° C.	52·1° C.
,,	V. ...	53·2° C.	53·3° C.	53·2° C.	53·4° C.

H. H. B. S.

On the Fractional Saponification of Oils and Fats. R. Henriques.—(*Zeit. angew. Chem.*, 1898, 338-345.)—By means of his method of cold saponification (ANALYST, xxi., 67 and 192) the author has thrown light upon the changes which

occur during the saponification of oils and fats. On saponifying saturated glycerides of known composition, such as tribenzoin, and a mixture of stearin and palmitin, with one-third of the alcoholic potash required for complete saponification, it was found that the glycerides were converted into the ethyl esters of the respective acids, whilst the whole of the glycerin present was found in the lye. Even with so little as 10 per cent. of the requisite alkali, nine-tenths of the glycerides were converted. For the separation of the esters from unchanged glycerides, advantage was taken of the fact that the former are volatile in a current of steam at 250° to 270° C., whilst the latter are only very slowly decomposed into fatty acids, which can readily be separated from the distillate. The apparatus recommended consists of an ordinary fractionating flask, whose outlet tube is connected with a Liebig's condenser. The flask is fitted with a cork with two holes, through one of which a thermometer passes, whilst the other is for a tube which conducts dry steam to the bottom of the flask. Between the steam generator and this tube is a small copper tube inclined at a slight angle upwards. This is heated with a small flame, and effectually prevents any particles of water from being mechanically carried into the flask. It is stated that with this apparatus 100 grammes of an ester can be distilled in from twenty to thirty minutes, and that the temperature is readily maintained constant.

For the experiments on unsaturated glycerides the following oils were chosen as types: (1) linseed, (2) olive, almond and rape, (3) castor. In each case ethyl esters were obtained by saponification with as little as 15 per cent. of the theoretical alcoholic potash, whilst practically the whole of the glycerin was liberated. No difference in the iodine and saponification value of the esters was observed on fractional saponification with varying quantities of alkali (33½ to 5 per cent.), and from this the author concludes that fractional saponification is of no value as a means of differentiating the fatty acids present in a given oil.

The ethyl esters from linseed-oil, separated by distillation and dried in a current of carbon dioxide, showed the following constants: Saponification value, 180·8; molecular weight, 309·7; iodine value, 168·4; acid value of liberated fatty acids, 198·7; molecular weight, 281·8. As was also observed in other cases, the difference between the molecular weights of the esters and of the fatty acids closely approximated to 28.

On distilling the esters obtained by saponifying linseed-oil with only 10 per cent. of the necessary potash, the glycerides left in the flask gave the following constants: Acid value, 1·1; saponification value, 185·8; iodine value, 174·4; acetyl value, 51·7. These figures correspond to a mixture of di- and triglycerides, but further investigation is required to determine whether an impure diglyceride was really present, and, if so, whether it was formed during the saponification, or during the distillation with steam.

By using methyl alcohol or amyl alcohol in place of ethyl alcohol, the corresponding methyl and amyl esters are formed. The latter are much less volatile than the ethyl esters, and the temperature in the distilling-flask must be raised to 270—280° C.

The ethyl esters of linseed fatty acids are very unstable, and readily oxidizable on exposure to air, finally yielding a substance insoluble in petroleum spirit. The changes which occur are illustrated by the following figures:

	Acid Value.	Saponification Value.	Iodine Value.	Acetyl Value.
Two days old	0	181·7	170·4	42·5
About three weeks	42	213·6	—	85·1
About six weeks	—	220·4	83·5	104·9
Substance insoluble in petroleum spirit ...	—	271·9	36·1	—

The author suggests that the increase in the saponification value is due to a disruption of the molecule and the formation of lower fatty acids. So long as the oxidized esters are soluble in petroleum spirit, they do not react with phenylhydrazine, but a marked reaction is shown by the insoluble substance. This is attributed to the presence of aldehydic or ketose groups. Unlike the linoxyn formed by linseed-oil on drying, the oxidation products of the esters are not solid products.

The distilled esters obtained from almond-oil gave the following constants: Saponification value, 185·0; molecular weight, 302·7; acid value of liberated fatty acids, 204·6; molecular weight of fatty acids, 273·7; iodine value, 91·1. An experiment in the case of rape-oil proved that the same changes occurred during hot saponification.

The glycerides of castor-oil were still more readily converted into esters than those of the other oils examined. The distilled ethyl esters had a saponification value of 174·9, and an iodine value of 84·1. They were less viscous than the original oil, and completely soluble, though not readily so in petroleum spirit. Their taste and physiological properties were found by Dr. Aronson to be the same as those of castor oil.

From these experiments, the author concludes that during the saponification (cold or hot) of all triglycerides with alcoholic potash, the ethyl esters of the acids present are first formed as intermediate products, with the complete liberation of the glycerin. Further investigation is required to determine to what extent the rule applies to esters other than glycerides. In the case of waxes an analogous behaviour is probable. C. A. M.

Contributions to the Analysis of Fat. W. Fahrion. (*Zeit. angew. Chem.*, 1898, 267-273.)—For the simultaneous determination of the saponification number (by Henriques' method) and of the amount of unsaponifiable matter the author recommends the following process: From 3 to 4 grammes of the oil are dissolved in 25 c.c. of petroleum spirit, 25 c.c. of approximately normal alcoholic potash or soda (containing not more than 5 per cent. of water) added, and after standing twenty-four hours the solution titrated with semi-normal acid, and the saponification number calculated from the results.

The neutral soap solution is washed into a separatory funnel and extracted with successive portions of 20 to 30 c.c. of petroleum spirit. The separate extracts are washed with 10 c.c. of 50 to 60 per cent. alcohol, the washings being returned to the funnel, and the extraction continued until the petroleum spirit leaves no residue on evaporation.

The following examples are given in illustration of this method:

	Saponification No.	Unsaponifiable Matter Per cent.
Beef fat	... 198·3	0·17
Lard	... 196·8	0·12
Palm-oil	... 199·7	1·07
Olive-oil	... 189·0	1·07
Cotton-oil	... 191·1	1·05
Rape-seed-oil	... 173·8	1·48
Castor-oil	... 178·6	0·59
Colophony	... 173·9	3·85

With reference to these results, the author remarks that the unsaponifiable matter of the palm-oil contained the coloring matter present, which, as has before been observed, became bleached on exposure to the air. Concordant results for the unsaponifiable matter, but not for the saponification number, were obtained with liver-oils, whilst there were considerable variations in both particulars in the case of wool-fat. This is accounted for by the fact that the latter contains lactones which on the addition of potash are converted into the salts of the corresponding acids, the conversion being the more complete the longer the contact with the alcoholic lye, and the saponification value being correspondingly raised. On subsequently treating the soap with dilute alcohol, a considerable quantity of these salts is reconverted into lactones, thus causing the variation in the amount of unsaponifiable matter.

The unsaponifiable matter from the various oils was tested according to Liebermann's method in the following manner: From 10 to 20 milligrammes were dissolved in about 3 c.c. of acetic anhydride, and 2 or 3 drops of concentrated sulphuric acid added to the cold solution. With the unsaponifiable substances from palm-oil, olive-oil, cotton-oil, rape-oil, castor-oil, and liver-oil a bright blue colour appeared, which rapidly changed to green, and finally, after an hour or more, to yellowish-brown. In the case of wool-fat the blue colour was not obtained, but the green was very bright.

In order to determine whether this might serve as an indication of the presence of cotton-oil in lard, the unsaponifiable matter was extracted from a mixture containing 10 per cent. of the oil and tested as above. There was an immediate blue colour, changing into green, whilst in the case of pure lard the blue was extremely faint, and only after a considerable time did a faint green tint appear. A similar difference was found in the fatty acids when examined by this test. Those from pure lard gave a faint yellow colour, and only after the lapse of fifteen minutes was a slight green coloration to be detected. On the other hand, the fatty acids from the lard containing the 10 per cent. of cotton-oil gave a yellow colour, which after two minutes changed into a well-marked green.

With the unsaponifiable matter from colophony Liebermann's reaction gave a characteristic violet colour, which rapidly disappeared (*Cf.* preceding abstract).

C. A. M.

The Liquid Fatty Acids of Seal Fat. E. Ljubarsky. (*Jour. prakt. Chem.*, 1898, lvii., 19-27.)—The fatty acids of a sample of Caspian seal fat, when converted into lead salts and treated with ether, yielded 17 per cent. of a solid fatty acid, apparently from its melting-point, palmitic acid, and 83 per cent. of liquid fatty acids, which were found to consist of oleic and physetoleic acids, the latter being the larger constituent, and yielding dihydroxy-palmitic acid on oxidation with alkaline permanganate. In the examination of the oxidation products, it was found that dihydroxy-palmitic and dihydroxy-stearic acids could combine to form a molecular compound, with physical properties quite distinct from those of its separate components. Thus, it melted at 120° to 124° C., solidified at 120° C., and was soluble in hot water, whereas dihydroxy-stearic acid is nearly insoluble. Attempts were made to obtain margaric acid by the action of phosphorus and iodine in the presence of water on this apparently dihydroxy-margaric acid, and subsequent reduction of the fatty iodide with nascent hydrogen, but without success, as the reduction products were invariably found to consist of a mixture of palmitic and stearic acids. C. A. M.

On the Precipitation of Proteids. H. Schjerning. (*Zeit. anal. Chem.*, 1898, xxxvii., 73-87.)—The facts that the same amount of proteid nitrogen is precipitated by ammonium sulphate and by zinc sulphate (Bömer, ANALYST, xxi. 16), and also by uranium acetate and phosphotungstic acid, although under different conditions (*Zeit. anal. Chem.*, xxxiii., 294), led the author to make experiments to determine whether similar salts of analogous metals would precipitate the same amount of nitrogen under similar conditions. Parallel determinations were made on the lines indicated in the author's previous paper (ANALYST, xxiii., 105), using solutions of diastase, peptone, egg albumin, milk and beer, and the following were the mean results obtained throughout the series:

	NITROGEN PER CENT. PRECIPITATED BY									
CHLORIDES.		ACETATES.		SULPHATES.						
Tin. ($SnCl_2$)	Lead.	Iron (Fe_2O_3).	Manganese (Mn_2O_3).	Magnesium.	Zinc.	Cadmium.	Nickel.	Iron (FeO).	Manganese (MnO).	Sodium.
5·1	6·4	63·0	60·8	41·8	40·0	38·2	35·5	37·5	44·3	43·4

The results obtained with chromium acetate were much too low, but this the author explains on the ground that the complete analogy between chromium and iron is doubtful.

Although copper salts present some analogies with salts of the magnesium group, precipitation with copper sulphate gave very much lower results either with or without saturation. For example:

	Magnesium.	Copper.	Iron.
Beer	17·4	4·5	—
Egg albumin	94·8	81·3	82·8

From this it appears that copper sulphate and ferrous sulphate precipitate almost the same quantities of nitrogen. Three metals which form a naturally ascending but

not analogous series are lead, copper, and mercury. With the acetates of these metals the following percentages of nitrogen were precipitated:

	Lead Acetate.	Copper Acetate.		Mercuric Acetate.	
		Cold.	Boiling.	Cold.	Boiling.
Beer	16·0	19·9	25·4	40·1	43·5
Wort	20·8	20·8	24·3	47·0	46·3

With regard to the influence of the acid, it was found that for the same metal the acetate precipitates more nitrogen than the sulphate, and the sulphate more than the chloride. With the latter the largest precipitation took place in the cold solution; with the other salts on boiling.

The acetates of calcium and strontium only precipitated 84·4 and 85·4 per cent. of the nitrogen of egg albumin respectively. Generally speaking, the precipitating power appeared to increase with the atomic weight in the analogous series.

The noble metals are unsuitable for the precipitation, chiefly on account of the readiness with which their salts are reduced to the metallic state.

The following facts have been established with regard to metals suitable for this purpose:

1. The sulphates and chlorides precipitate at most only true albumins, and these often incompletely.

2. The acetates of the magnesium group and of the extended magnesium group precipitate only true albumins. The precipitating power appears to rise with the atomic weight.

3. The acetates of lead and its analogues (?) precipitate all the proteids up to the pro-peptones (albumoses).

4. The acetates of the analogous oxides, Fe_2O_3 and Mn_2O_3, precipitate all proteids up to the real peptones.

5. Uranium acetate and phosphotungstic acid precipitate all the proteids, being examples of the analogous metals uranium and tungsten, although not of the same salts. Uranium acetate can also precipitate some of the ammoniacal nitrogen in the presence of phosphoric acid, whilst phosphotungstic acid precipitates the whole of the nitrogen in that form.

With regard to mercury, which the author looks upon as a transition metal between the heavy non-noble and the noble metals, the following particulars are given: The chloride precipitates all proteids up to the pro-peptones; in other words, the same amount of nitrogen as is precipitated by lead acetate. Mercuric acetate precipitates all the proteids, and, in addition, more or less of the amide nitrogen present. It is well known that mercury forms amido compounds insoluble in acetic acid. Hence the author considers this salt even less suitable than copper acetate for the quantitative precipitation of proteids.

The author draws a distinction between precipitations carried out in the method described and precipitations by saturation. The former he attributes to a definite chemical reaction, whilst in the latter case there is probably a withdrawal of the solvent. He considers it probable that all easily soluble sulphates would precipitate

all albumins and pro-peptones if added to saturation in the presence of a little acetic acid.

From the positive results obtained with the salts of analogous metals, and the negative ones with metals of non-analogous series, the author concludes that the proteids precipitated by the former are definite individuals. C. A. M.

Testing Varieties of Glue. R. Kissling. (*Chem. Zeit.*, xxii., 171.)—The author has examined two recent methods for testing glue, viz., Stelling's (*Chem. Zeit.*, xx., 461) and Fels' (*Chem. Zeit.*, xxi., 56). Stelling's method consists in the determination of the matter other than glue, and depends upon the fact that when glue is treated with alcohol of 72 per cent. it gives up to it a certain quantity of fatty matter and some substances of an extractive nature, the gelatin being insoluble. Fels' method consists in the determination of viscosity. The two methods were compared with that of the author previously published (*Chem. Zeit.*, xvii., 726), which consists in determining the firmness of the jelly by observing the length of time taken for rods of glass, zinc, and brass to sink through it. The results were not very satisfactory, though a certain parallelism was noticeable between the jelly firmness and viscosity, and Stelling's process showed that those glues yielding the firmest jellies contained the smallest proportion of matter not gelatin.

In most cases the value of glue depends so greatly upon the purpose for which it is intended to be used that a knowledge of this is requisite in judging of its suitability. If freedom from smell combined with firmness and freedom from acidity be required, the best leather-glue should be chosen; if, however, adhesive property be the only consideration, the cheaper bone-glues suffice. H. H. B. S.

Analysis of Raw Materials containing Tartaric Acid. J. Schäfer. (*Chem. Zeit.*, xxii., 255 and 269.)—Of all methods that have been proposed for the determination of tartaric acid in lees, argol, tartar, etc., the most widely adopted is the hydrochloric acid method of Goldenberg, of which the following is a brief description: The tartaric acid in the sample is set free by hydrochloric acid, excess of potassium carbonate added, and the solution boiled to convert the tartaric acid into its neutral potassium salt. The solution of this is then concentrated by evaporation to about 10 c.c., precipitated by glacial acetic acid in the presence of alcohol of 96 per cent., and the precipitate filtered off, washed, dissolved in hot water, and titrated hot with soda solution. It appears, however, as the following experiments show, that this method yields results above the truth: Two 50 c.c. portions of the same hydrochloric acid solution being taken, each was treated exactly as Goldenberg directs, except that in one case alcohol of 30 per cent. was used instead of alcohol of 96 per cent. After standing for six hours each was filtered, washed, and titrated. An experiment was then made to ascertain how much acid tartrate would remain in solution in 30 per cent. alcohol. To this end 1·5 grammes of pure cream of tartar were treated as directed by Goldenberg, with the exception that 30 per cent. instead of 96 per cent. alcohol was used. Now, if to the quantity of tartaric acid found on using alcohol of

30 per cent. be added the quantity found in solution in the alcohol, the total should correspond with that found on using alcohol of 96 per cent. With the exception, however, of high-testing or good samples, this was found to be almost invariably not the case. A few examples are given in the following table:

Material examined.	C.c. $\frac{N}{10}$ Soda Solution required when Alcohol of 96 per cent. was used.	C.c. $\frac{N}{10}$ Soda Solution required when Alcohol of 30 per cent. was used.	C.c. $\frac{N}{10}$ Soda Solution corresponding to the dissolved Tartrate.	C.c. $\frac{N}{10}$ Soda Solution corresponding to the total Tartrate.	Difference between the number of c.c. Soda Solution used.	Difference in per cent. of Tartaric Acid.

,, ,, ...	50·53	49·00	1·50	50·50	—	—
French wine lees ...	45·80	41·94	1·80	43·74	2·06	1·03
,, ,, ,, ...	50·32	47·87	1·50	49·37	0·95	0·47
Spanish wine lees ...	60·96	56·88	2·00	58·88	2·08	1·04

The high results obtained when alcohol of 96 per cent. is used appear to be due to the separation of a fatty body, which combines with soda, and so vitiates the titration. Its separation with the precipitate increases in proportion to the length of time the solution is allowed to stand after the addition of the acetic acid and alcohol. The difficulty, however, can be almost, if not completely, overcome by extracting the fat from the sample with alcohol and ether previous to the determination, which is shown by the following results:

Material examined. Extracted previous to the determination with Alcohol and Ether.	Per cent. of Tartaric Acid found on filtering immediately.	Per cent. of Tartaric Acid found on standing for twelve hours.	Difference per cent.
Italian wine lees	29·33	29·38	0·05
Spanish wine lees ...	25·27	25·37	0·10
,, ,, ,, ...	28·60	28·70	0·10
Algerian wine lees ...	22·32	22·32	

The choice of an indicator for the titration is also an important matter. When azolithmin is used, the change of colour takes place very slowly—much more slowly, in fact, than in the titration of mineral acids, owing to the formation of Rochelle salt, and the larger the quantity formed, the slower the change. This holds good in the titration of chemically pure acid potassium tartrate, but in the case of lees and tartars the indication is further vitiated by the presence of phosphates.

The following general conclusions are drawn:

1. Feebly red litmus-paper should be used as the indicator.

2. After the addition of the acetic acid and alcohol, the solution should be well stirred and immediately filtered off.

3. The risk of too high results on standing can be minimized by extracting the fat by alcohol and ether previous to the determination. H. H. B. S.

Determination of Ash in Crude Sugars and Saccharine Liquids. G. Morpurgo. (*Chem. Zeit.*, xxii., 257.) The following process has been found suitable for the determination of the ash in Samos wine, which contains up to 20 per cent. of sugar. The residue left on evaporation is mixed with about one-third of its volume of hydrogen peroxide, and carefully evaporated over a naked flame until the mass becomes quite brown. After cooling, a few drops more of hydrogen peroxide are added, and the mass dried and ignited. In many cases quite a low red heat is sufficient to convert the residue into a pure white ash. Should this, however, not be the case, a little hydrogen peroxide is dropped upon the parts where the incineration is not complete, and the residue again dried and ignited.

The action of the hydrogen peroxide is mechanical as well as chemical. Small bubbles of oxygen being liberated throughout the mass render it porous and easily consumed at a comparatively low temperature, and of course the enclosed oxygen assists the combustion.

The method is also applicable to the incineration of drugs. H. H. B. S.

Two Colour Reactions for Pyruvic Acid. L. Simon. (*Bull. Soc. Chim.*, 1898, xix., 294, 295.)—Pyruvic acid ($CH_3.CO.COOH$) gives with potassium and sodium nitroprusside a strong violet-red coloration. One c.c. of the solution containing the acid is mixed with the same volume of a solution of potassium hydroxide (specific gravity 1·15 to 1·20), and several drops of a freshly-prepared and fairly-concentrated solution of sodium nitroprusside added. When the acid is only present in traces, the solution should be compared with the alkaline solution of nitroprusside, which itself has a yellow tint. In this way it is possible to detect 1 part of pyruvic acid in 50,000.

The addition of acetic acid to the coloured solution makes the shade a more pronounced violet, but an excess of acetic acid dispels the colour.

The salts and esters of pyruvic acid give the same reaction, but the compound with phenyl-hydrazine gives a negative result. Phenyl-glyoxylic ($C_6H_5.CO.COOH$) acid and its derivatives do not give any coloration, but the reaction is obtained with many other substances (aldehydes, ketones, acetone, etc.). It is, in fact, Legal's reaction, in which, according to Denigés, the coloration is, as a rule, due to the $CH_2.CO$ group, when the carbonyl is not united directly to a certain number of monovalent radicles. Thus, this test, though very sensitive with pyruvic acid, is not characteristic of it alone.

The colour obtained, however, on adding ammonia to pyruvic acid and then nitroprusside does not appear to be given by any substances except that acid and its derivatives and by acetophenone, distinguished by giving a very stable blue colour in Legal's reaction. To 1 c.c. of the solution to be tested are added 1 c.c. of a concentrated solution of ammonia and several drops of the nitroprusside. A

violet-blue colour slowly appears with pyruvic acid, the limit of sensibility being about 1 in 10,000. The appearance of the coloration is accelerated by gentle heat, but the colour disappears on boiling, or on the addition of an excess of acetic acid.

On adding amines of the fatty acid series to nitroprusside and pyruvic acid, a pronounced violet colour rapidly appears; on the addition of acetic acid, this changes to blue and then disappears. This reaction is quite distinct from that given with ammonia. The colour appears more rapidly, but is more evanescent, especially in the presence of acetic acid; whereas in the case of the ammonia, the addition of a small quantity of acetic acid makes the colour more pronounced. C. A. M.

Reducing Action of Filter-Papers. H. Jervis. (*Chem. News*, lxxvii., 133.)—The author has made experiments to ascertain the reducing action of filter-paper upon chromate solutions by digesting various descriptions of paper in hot and cold solutions for half an hour.

Each paper (12·5 cm. diameter) was digested in 25 c.c. of a solution of potassium chromate (1 c.c. = 0·01 gramme Fe) diluted to 200 c.c. In one set of experiments the solutions were made acid with 50 c.c. of normal sulphuric acid, and in another set alkaline with 50 c.c. of normal sodium hydrate. The following table shows the potassium chromate left after digestion in terms of cubic centimetres of the original solution:

12½ cm. Paper.	Ash.	Cubic centimetres K_2CrO_4 Hot.		Cold.	
		Acid.	Alkali.	Acid.	Alkali.

INORGANIC ANALYSIS.

Determination of Lead in Water. A. Liebrich. (*Chem. Zeit.*, xxii., 225.)—The crude sulphide precipitated by sulphuretted hydrogen is converted into sulphate by incineration and treatment with a few drops of nitric and sulphuric acids. This is then dissolved in a few c.c. of warm potash solution (1 : 10), the solution filtered, made up to 20 c.c., 2 c.c. of ammonium sulphide added, and the lead determined colorimetrically by comparison with the colour of equal volumes of similar solutions containing known quantities of lead. 0·001 gramme of lead in 10 c.c. is a suitable strength for a stock solution. 1 c.c. of this diluted to 20 c.c. will

give a strong brown colour on addition of 2 c.c. of ammonium sulphide. A gravimetric determination can also be made in the solution used for the colorimetric test by warming it and filtering off the lead sulphide, washing with water containing a little acetic acid, incinerating in a porcelain basin, and converting into sulphate by treatment with nitric and sulphuric acids. By working upon 1 litre or more of water, very exact results can be obtained. H. H. B. S.

The Estimation of Cerium in the Presence of other Rare Earths. G. von Knorre. (*Zeit. angew. Chem.*, 1897, 685-688.)—This is based on the fact that the yellow-colour ceric salts are reduced by hydrogen peroxide in the presence of free acid to colourless cerous salts, as in the equation:

$$2Ce(SO_4)_2 + H_2O_2 = Ce_2(SO_4)_3 + H_2SO_4 + O_2.$$

The cold solution of the ceric salt is mixed with an excess of a dilute solution of hydrogen peroxide, of which the strength is known, and when all colour has disappeared the excess of peroxide is titrated back with permanganate.

If the permanganate solution be standardized on an iron solution, the amount of cerium present may be expressed in terms of iron, 56 parts of the latter being equivalent to 140 parts of cerium. It is advisable to use a dilute solution of permanganates (not containing more than 2 grammes of $KMnO_4$ per litre).

Notwithstanding Rose's statement that potassium permanganate is slowly decolorized by a solution of cerous sulphate, the author finds that the end-reaction can be readily recognised. With a freshly prepared acidified solution of a ceric salt the reduction takes place instantaneously, but if the solution has been exposed to the air for some time, as long as fifteen minutes may be necessary for complete decolorization. The results obtained, however, in both cases are identical. By boiling an old solution after the addition of sulphuric acid, and cooling before adding the hydrogen peroxide, the rate of reduction is accelerated, and the reaction takes place almost as rapidly as in a freshly prepared solution.

Either sulphuric acid or nitric acid may be used, but it is essential that the acidification shall take place before the addition of the hydrogen peroxide, since otherwise by-reactions occur and the results are too high. C. A. M.

A Colorimetric Method of determining Silica in Water. A. Jolles and F. Neurath. (*Zeit. angew. Chem.*, 1898, 315, 316.)—This is based on the fact that alkaline molybdates form in the presence of free nitric acid characteristic yellow compounds with silicic acid similar to those produced with phosphoric and arsenic acids. Of the alkaline silico-molybdates, the potassium compound is the most soluble, and its aqueous solution also possesses the most intense yellow coloration. This gradually increases as the temperature rises, and reaches its maximum at 70° to 80° C.

In the application of this reaction to the determination of silica in water, the authors employ a solution of potassium molybdate, prepared by dissolving 8 grammes of the salt in 50 c.c. of water, and adding 50 c.c. of nitric acid (specific gravity 1·2).

One c.c. of this reagent is added to 20 c.c. of the water under examination, and at the same time to each of several glass cylinders of the same dimensions which contain dissolved in 20 c.c. of distilled water known quantities of silica in the form of soluble glass. The cylinders are placed in a water-bath, the temperature gradually raised to 80° C., and the colour produced in the sample of water compared with that of the standard samples.

It is improbable that phosphoric acid would be present in sufficient quantity in 20 c.c. of water to influence the results, whilst arsenic acid would not be met with in ordinary water. In any case, however, a quantity of the water may be evaporated to dryness several times with nitric acid in order to remove silica, the residue treated with water, the solution filtered and made up to the original volume, and 20 c.c. tested with the molybdate solution as above. Should no yellow coloration appear, phosphoric and arsenic acids must be absent; whilst, on the other hand, if a positive result be obtained, the amount may be determined as silica, and deducted from the result previously found.

The results obtained in this way are compared with those given by the ordinary gravimetric method in the subjoined table:

	Direct Colorimetric Determination.		Gravimetric Method.
	Silica in 20 c.c.	Milligrammes per litre.	Milligrammes of Silica per litre.
Deep-well water ...	0·00006 gramme	3	2·9
Spring water ...	Between 0·0004 and 0·0002, but nearer to 0·0004 = 0·00035	17·5	15·6
,, ,, ...	0·0002	10	9·3
,, ,, ...	Between 0·0006 and 0·0004, but nearer to 0·0004 = 0·00045	22·5	21·2

C. A. M.

The Determination of Oxygen Dissolved in Water. Albert Levy and F. Marboutin. (*Bull. Soc. Chim.*, 1898, xix., 149-151.)—The water to be examined is introduced into a double-stoppered pipette, is made alkaline with potash, and a known volume of ammoniacal ferrous sulphate added. Potassium sulphate is formed, and the ferrous hydrate precipitated is partially transformed into ferric hydrate by the oxygen present in the water. To determine the amount of ferric hydrate produced, an excess of sulphuric acid is added to convert both oxides into sulphates, and the residual ferrous sulphate estimated by means of standard permanganate, and deducted from the quantity originally added. In order to avoid the error introduced by the action of the permanganate on the organic matter contained in certain waters, a blank determination is made on the same water. Experiments are described to prove that the temperature and length of time of the reaction have no influence on the results (*cf.* ANALYST, this vol., 52). C. A. M.

Titration of Thiosulphate with Iodic Acid. C. F. Walker. (*Zeits. anorg. Chem.*, 1898, xvi., 99.)—This article consists of a detailed examination into the method lately suggested by Riegler (ANALYST, xxii., 25) for the estimation of thiosulphate by titration with standard iodic acid. The results show that the process is inaccurate; for not only is the appearance of the blue colour at the end of the reaction wanting in sharpness, but the reaction itself is accompanied by some regeneration of thiosulphate, which causes the figures to be largely dependent upon the volume and concentration of the liquids employed, as well as on the time taken in the operation.

The purest iodic acid of commerce often contains an excess of iodine, probably because it consists partly of anhydride. It may be obtained of theoretical composition by recrystallization and drying over sulphuric acid at atmospheric temperatures; while, as stated by Riegler, its solution maintains its original strength unchanged in the dark for at least four months. F. H. L.

Specific Gravity Tables for Hydrofluoric Acid. (*Chem. Zeit.*, xxii., 225.)—The following tables showing degrees Baumé, specific gravity, and strength of solutions of hydrofluoric acid have been prepared at the experimental station of J. L. C. Eckelt, Berlin:

°Bé.	Sp. gr.	HF%.	°Bé.	Sp. gr.	HF%.	°Bé.	Sp. gr.	HF%.

H. H. B. S.

Estimation of Free Sulphuric Acid in Superphosphates. D. Crispo. (*Rev. Chim. Anal. appl.*, v. [24], 482.)—In view of the errors attaching to the only method of determination hitherto published (extraction of the free acids by alcohol and precipitation by barium chloride from a hydrochloric solution), the author recommends the following as giving exact results and enabling small quantities of sulphuric acid to be estimated in the presence of very considerable amounts of phosphoric acid.

The superphosphate is extracted with strong alcohol, and the dry matter left on the evaporation of the solvent is taken up with absolute alcohol. The insoluble

residue then remaining is dissolved in hydrochloric acid, boiled to convert the meta- and pyro-phosphoric acids into the ortho-acid, and after eliminating this latter, the sulphuric acid is determined by means of barium chloride. C. S.

On the Reduction of Sulphurous Acid to Sulphuretted Hydrogen. E. Donath. (*Zeit. anal. Chem.*, 1897, xxxvi., 663-665.)—It is well known that sulphurous acid, itself a reducing agent, is comparatively easily reduced. Thus a hot solution of stannous chloride reacts with sulphurous acid, probably in accordance with the equation, $3SnCl_2 + SO_2 + 6HCl = 3SnCl_4 + 2H_2O + H_2S$. If too much hydrochloric acid be not present, a precipitate of stannic sulphide or of a mixture of stannous and stannic sulphides is obtained. This reaction has the following analytical applications:

Detection of Arsenic and Antimony in presence of large quantities of Tin.—The solution under examination is mixed with a freshly-prepared strongly acid solution of stannous chloride, the mixture heated to boiling, and a solution of sodium sulphite or of sulphurous acid added drop by drop. The sulphides of arsenic and antimony are precipitated whilst the tin remains in solution.

Detection of Arsenic in Vitriol.—From 10 to 15 c.c. of the commercial acid are diluted with an equal volume of water, and treated as above. When arsenic is present, there is a separation of finely-divided arsenic sulphide after warming for some time, whilst in other cases there is only a strong opalescence due to the separation of sulphur. C. A. M.

A New Gas-Volumetric Method for the Determination of Nitrous Acid and other Substances Oxidizable by Hydrogen Peroxide. E. Riegler. (*Zeit. anal. Chem.*, 1897, xxxvi., 665-668.)—This is a differential method which consists in oxidizing the acid with hydrogen peroxide, in accordance with the equation $HNO_2 + H_2O_2 = HNO_3 + H_2O$, and then determining the volume of oxygen yielded by the excess of the reagent in contact with permanganate. A blank determination is made with a similar quantity of hydrogen peroxide under the same conditions, and the difference between the two results gives the amount of oxygen taken up by the nitrous acid. One c.c. of oxygen at 0° C. and 760 mm. corresponds with 0·0034 gramme of N_2O_3. For measuring the gas the author prefers a modification of the Knop-Wagner azotometer.

In making a determination, 5 c.c. of hydrogen peroxide solution containing not more than 1 to 1½ per cent. of hydrogen peroxide are placed in the flask, together with 30 c.c. of water and about 10 c.c. of concentrated sulphuric acid, whilst a few crystals of permanganate (about 0·1 gramme) are placed in the small inner vessel. The flask is then connected with the measuring-tube, shaken until a permanent pink colour is produced, and the liberated oxygen collected and reduced to standard temperature and pressure. Let the volume equal V_0.

The flask is then washed out, and about 30 c.c. of the solution of nitrous acid (which must not contain more than 0·15 per cent. of N_2O_3) introduced, together with 5 c.c. of hydrogen peroxide solution and 1 or 2 drops of sulphuric acid. The flask is shaken, allowed to stand for about five minutes, and then 10 c.c. of sulphuric acid

gradually added. The crystals of permanganate contained in the inner vessel are then allowed to come into contact with the solution, and the gas collected and measured as before. If this volume be taken as v_0, the amount of nitrous acid is obtained from the formula $\frac{V_0 - v_0}{2} \times 0{\cdot}0034$, or $(V_0 - v_0) \times 0{\cdot}0017$.

In a similar manner the amount of iron contained in a ferrous salt can be determined; in which case $(V_0 - v_0) \times {\cdot}00025$ equals the amount of oxygen corresponding to the iron oxidized to a higher state. The results obtained are said to be excellent.

Potassium permanganate and sulphuric acid may be replaced by silver oxide, the oxidation being then carried out as follows: Ten c.c. of the 1 per cent. solution of hydrogen peroxide, 40 c.c. of water, and 15 drops of a 15 per cent. solution of potassium hydroxide are introduced into the flask, whilst in the inner vessel are placed 5 c.c. of a 3 per cent. solution of silver nitrate. The gas is collected and measured and a second determination made, using 10 c.c. of the hydrogen peroxide solution, 40 to 50 c.c. of the dilute nitrite solution, and 1 or 2 drops of sulphuric acid. The amount of nitrous acid is then calculated from the formula $(V_0 - v_0) \times 0{\cdot}0034 = N_2O_3$.

C. A. M.

Sodium Peroxide in the Quantitative Analysis of Coal, Coke, and Asphalt. C. Glaser. (*Jour. Amer. Chem. Soc.*, 1898, xx., 130-133.)—Clark (*Jour. Chem. Soc.*, 1893, 1079) states that the action of sodium peroxide on coal and coke is too violent to allow of its use in their analysis, but the author finds that it can be successfully used for the determination of sulphur in coal, coke, and asphalt in the following manner:

The material is placed in a large silver or nickel dish, and covered with about four times its weight of sodium carbonate, on which is laid a piece of sodium hydroxide of about half the weight of the carbonate. The dish is moved slowly over a small flame, until the evolution of gas has ceased and a half-fused mass obtained. On this sodium peroxide is dusted in successive small quantities until the reaction is over and the carbon has been completely burned away. If necessary, the mass is then completely fused; but this is usually brought about by the heat of combustion, which takes place quietly and without loss by explosion or spurting. The determination of the sulphur is then completed in the usual way. The time required for combustion is said to be about five minutes for coke, ten for coal, and a little longer for asphalt.

C. A. M.

The Analysis of Coal. F. Haber and S. Grinberg. (*Zeit. anal. Chem.*, 1897, xxxvi., 557-567.)—One of the principal difficulties in the determination of the calorific power of coal by estimating the carbon and hydrogen is that the temperature required to burn the methane with copper oxide is often sufficient to melt the combustion-tube. The authors obviate this by making the combustion in the presence of platinized asbestos. The first 3 cm. of the combustion-tube (43 cm. in length) are left blank, then comes a plug of copper (1 cm.), a layer of granular lead chromate (6 cm.), and a second plug of wire gauze (0·5 cm.). Next comes 1 gramme of finely-divided platinized asbestos (10 to 20 per cent.), which is loosely packed so

as to occupy about 10 cm. of the tube, and finally a third copper gauze plug. The remainder of the tube is left empty, and is closed at the end with a rubber stopper fitted with a T-piece, through the horizontal part of which passes a copper wire with a platinum end, bent into a hook.

By means of this the platinum boat can be moved backwards or forwards within the tube. The other end of the combustion-tube is connected with the usual absorption apparatus, and the part of the tube containing the materials and that occupied by the boat is wrapped in thick copper gauze. For the combustion two Tecla burners are used.

About 0·25 gramme of the finely-powdered coal is placed in the boat, which is introduced into the tube whilst a slow current of oxygen is admitted through the T-piece. After several minutes the boat is pushed forward a little, and so on by degrees until it touches the wire-gauze plug. Care must be taken that the coal does not do more than burn with a red glow, otherwise the combustion is too rapid. In the authors' experience the amount of nitric and nitrous acids found in the absorption-tubes was in every case very trifling, the former being invariably less than 0·05 per cent. Sulphuric acid was never found. The table giving the analysis of several different kinds of coal shows that this method gives results in close agreement with those obtained by the ordinary method of combustion with copper oxide.

C. A. M.

MISCELLANEOUS.

THE LATE MR. F. P. PERKINS.

It is with regret that we have to record the death, at the age of sixty-six years, of Mr. Frank P. Perkins, which took place on June 19. The deceased was one of the oldest Public Analysts in the kingdom, having been twenty-six years Public Analyst for the city of Exeter. He contributed a number of papers to the earlier volumes of the Analyst, on the analysis of butter-fat, the determination of organic carbon in water residues, the estimation of nitrates in river water, the discrimination between oxygen absorbed by nitrites and by organic matter, and on other subjects. He was a member of the Society of Public Analysts for nearly twenty years, having been elected in 1880.

THE ANALYST.

AUGUST, 1898.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

SUMMER MEETING.

THE summer meeting of the Society this year took the form of a visit to the Duke of Bedford's estate at Woburn, for the purpose of inspecting the Agricultural Experimental Station which has been conducted there for many years by Dr. Voelcker, under the auspices of the Royal Agricultural Society of England. On the morning of Tuesday, July 12, a party of about forty (including a large proportion of ladies) met at Euston and travelled to Bletchley, where, after changing trains, they were conveyed to Woburn Sands Station. Conveyances were in readiness, and after a drive of some three miles through very pretty country the main experimental field, called "Stackyard Field," was reached. Here the various plots of wheat and barley were inspected. Some of these had not received applications of any kind for twenty-two years, others had been treated every year with sulphate of ammonia or with nitrate of soda alone, others with mixtures of various chemical fertilizers, others, again, with farmyard manure. The members accordingly were able to estimate for themselves the influence exercised by the different methods of treatment. All the details were explained by Dr. Voelcker as the party moved on past the various plots, and attention was drawn to the most striking features. Each member of the party was, in addition, provided with a pamphlet, giving plans of the various experiments, the treatment to which each plot had been subjected, and the yield over a series of years. After viewing the fields, the company were conveyed to the experimental pot-culture station, where they inspected the laboratory and also a number of experiments, conducted in pots, designed with a view to discovering the effects on agricultural crops of compounds of some of the rarer elements, such as iodine, bromine, fluorine, lithium, manganese, titanium, etc. This department had only quite recently been established, but several results of an interesting and unexpected nature have already been obtained. After this the party sat down to an excellent luncheon, laid out in the large greenhouse belonging to the station, during which, on the proposition of the President (Dr. Bernard Dyer), a vote of thanks to Dr. Voelcker for his kindness was carried by acclamation, Dr. Voelcker saying, in reply, that the inception of the visit was really due to the fact that the Society had this year an "agricultural president." After luncheon the party were conveyed through the beautiful grounds of Woburn Park to Woburn Abbey, which is the principal seat of the Duke of Bedford. Here the

picture and sculpture galleries and other interesting collections were visited. The weather was most propitious, and the general arrangements were well and carefully organized, the result being a most agreeable, entertaining, and instructive day.

SEWAGE ANALYSIS AND STANDARDS OF PURITY FOR EFFLUENTS.

By C. G. Moor.

(*Read at the Meeting, June* 1, 1898.)

Crude sewage as brought to purification works necessarily varies from town to town. It varies in composition according to the presence or absence of abnormal institutions, such as factories, and according to the manner of its collection; for example, as to whether this is from a high level by continuous gravitation, or from a low level by continuous pumping. The latter is a matter of considerable importance, because in the older precipitation processes it was very difficult to deal with sewage that was stale, as it always is when collected from a low-level system, which is pumped during a few hours only of the working day.

Sewage varies in quantity and in concentration, primarily, according to the extent of the water supply in gallons per head of population, and, secondly, according to the rainfall, etc.

In a given town it varies in all respects from hour to hour, and, as a rule, to a less extent from day to day and from season to season. The extent of none of these variations can be stated in advance. In the estimation of the relative efficiency of the purifying processes used at different towns, it is therefore the ratios of the measurable factors of impurity in the effluent to those in the crude sewage from which it was derived, that must be compared so far as it is possible to obtain them.

In the case of sewage farms these are difficult to obtain. The sewage which is spread over a field will not all find its way into the effluent. Some will be absorbed in the ground, and there disintegrated by the action of micro-organisms and of higher plants.

This is the purification process proper, and its extent will vary up to a limit with the extent of saturation of the soil with previous additions of sewage.

Another part may, however, be temporarily arrested, and the interval which elapses before it is washed through may vary, not only with the nature of the ground and of the crops, but with meteorological and other conditions. This is not necessarily a process of purification, and the comparison of the effluent with the crude sewage may be improperly favourable or unfavourable to the process, according to the time at which the effluent was taken. Evaporation from the surface of the sewage-field will in all cases tend to exhibit the degree of purification as less than it actually is, and less to an extent varying with the presence and nature of the drainage and with the temporary condition of the soil in respect to saturation with sewage. Dilution by rain will affect both sewage and effluent, though possibly not to the same extent; but a more serious variable is the height of the ground-water, which may dilute the

effluent to an extent which would altogether vitiate any figures that did not take account of it.

These are only some of the factors affecting sewage-farms, which are liable to vary beyond control and to some extent beyond measurement. They are indeed inevitable in any system in which provision is not made for the uniform treatment of all parts of the crude sewage.

In the artificial processes, whether chemical, electrical, bacterial, or bacterio-mechanical, the difficulties in the way of obtaining comparable figures are considerably less.

In all of them the whole of the sewage is subjected to a uniform treatment, the interval between the inlet and outlet is known, and the factors of variation between town and town, hour and hour, day and day, may be expected to affect the constitution of the effluent no less than that of the sewage, or at least to affect it to an extent so small as not to seriously invalidate the comparison it is desired to make.

The following scheme of observations would be applicable in most cases where the question to be settled is the efficiency of a particular process at a particular place:

Town Variables.

1. Note nature and extent of factories or other abnormal sources of pollution.
2. Chart the water-supply for previous week and for period of experiments, and ascertain that it is normal.
3. Chart rainfall during the experiments and for the previous week.
4. Note the temperature of the air and sewage during experiments.

Works Variables.

1. Ascertain dimensions of works, the length and fall of sewers, and the general structural details of works and sewerage, and whether pumping is required—*i.e.*, are there low-level sewers?
2. Chart the volume of sewage at intervals during the experiments.
3. Where screens are in use, estimate the solids they retain.

Sewage Variables.

1. Take samples at intervals during the first twenty-four hours of sewage and effluent, determine the chlorine and loss on ignition for each, and compare the result. with that of an average sample taken in quantities proportional to the flow for the time being during the working day, measured so as to include the time of maximum impurity. If these factors give sensibly the same results as average samples, the remainder of the investigation can be conducted on average samples. All samples, average or otherwise, must be kept in ice from the time at which they were taken up to the time of examination, and the interval should be as short as possible.
2. The following estimations and observations should be made:

PHYSICAL EXAMINATION.

Smell.

Colour.—Whether any in one inch in white dish.

Turbidity and determination of suspended matter, if present.

CHEMICAL EXAMINATION.

Total Solids.

Mineral Solids.

Loss on Ignition.—I attach considerable importance to this, and shall refer to it later on.

Chlorine.—This figure is of high value in enabling us to identify the effluent with a sample of sewage with which it is desired to compare it. If one goes to a sewage works at 11 or 12 o'clock, when the sewage is foulest, and takes samples of the raw sewage and of the effluent, they will almost invariably not correspond. An example of this is shown in the case of some analyses made for the Manchester Corporation, the figures of which appeared in the *Sanitary Record* for May 27. A sample of raw sewage contained 14·9 grains of chlorine per gallon, whereas the effluent contained only 6·3 grains per gallon, showing that the sewage corresponded to a period of considerable impurity, while the effluent was probably derived from sewage that was not nearly so foul.

Hardness.—Considerable hardness is produced on adding the large quantities of lime sometimes employed, as in Hansen's process, in which lime and sulphurous powder are used, or in other processes where lime and alumina salts are used.

Nitrites.—I regard the presence of these as showing a want of free access of oxygen. They are not often found in effluents unless the latter have been bottled up and kept in the laboratory for some days, in which case nitrites are always present in large quantities.

Nitrates.—If we determine that nitrates ought to be present in definite quantities, it will probably compel those works at which precipitation is practised to add filter-beds to their plant. The presence of nitrates in the effluent is highly desirable, as showing that oxidation has proceeded to some extent, and that true purification has therefore begun, and some figure should be provisionally fixed so that at least a certain quantity of oxidized nitrogen should be present.

Saline Ammonia.—This cannot be objected to as a natural step in the breaking down of nitrogenous matter.

Albuminoid Ammonia.—The lower the quantity of this, the better.

Oxygen Absorbed.—Four hours at 80° F., Tidy's modification of Forschammer's process.

3. Chart the temperature of sewage and effluent. In some bacteriological processes there is reason for supposing that the temperature rises during the operation.

The following supplementary estimations from a bacteriological point of view would add greatly to the interest of the determinations above mentioned:

1. The number of bacteria, in both sewage and effluent, that grow on gelatin, and the number that liquefy that medium. These determinations will be of comparatively little value unless the following estimations are also undertaken, namely, an estimation of those organisms that live at blood-heat, and of the anaërobic bacteria present, which must, of course, be cultured in a neutral gas under special conditions.

In addition, the investigation of the bacterial contents of the effluent in particular would not be complete without a special estimation of the nitrifying bacteria, which

only grow on special media, such as silica jelly. From these considerations it will be conceded that a bacteriological investigation (even if we had the power of duly interpreting the results when obtained) would be no light matter; and in the present state of our knowledge it could not yield results of anything like the practical value that we can derive from a chemical examination.

In regard to the relative importance of the chemical processes, I will not go over ground which is obviously familiar to all of us; but I would draw special attention to the determination of the "loss on ignition" as being one of the most important factors for characterizing a sewage in respect of its richness in organic matters. Personally, I think that for this purpose it is to be preferred as a characteristic estimation to the results of the popular "oxygen-absorbed" process. For instance, cellulose in various forms occurs in considerable quantities in sewage, and this, while it would probably not be attacked by the permanganate used in the "oxygen-absorbed" process at blood-heat, would certainly be liable to undergo bacterial decomposition and to produce offence. No doubt this would come out in the determinations of organic carbon and nitrogen which have been recommended by a high authority for the examination of sewage.

It must be remembered, however, that life is short, and these processes are long; and it is in the belief that their adoption would tend to the limitation of the number of determinations, and, through this, cause a far greater loss in useful information than would be gained by their practice, that I have intentionally omitted them from my list.

By proceeding as I have described, the principal factors affecting the efficiency of sewage purification processes can be obtained, and while the selection of observations which I have made is subject to criticism, there will be probably little fundamental differences between us as to the necessity and sufficiency of such observations or their equivalents. The interpretation of these results is, however, a matter of more complexity, and more likely to excite differences of opinion. On that ground, and rather with the object of drawing discussion than of formulating any final statement, I submit certain considerations which appear to me to be fundamental. In the first place I am convinced that the purification of sewage, so far as it is contemplated by any existing scheme, can only be regarded as a chemical process, and that it is in terms of chemical determinations alone that the results of any process for effecting it can be expressed. I do not lose sight of the fact that the processes (which through the industrious genius of one of our members, and of others who have worked on similar lines, have now been shown to be the most promising) are bacterial; but it must be clearly remembered that the bacteria so involved are merely means for applying biological energy in place of the chemical energy previously employed, and are used for the precisely identical purpose of altering the sewage in its chemical composition, from a substance highly favourable to the growth of putrefactive and some other organisms, into a substance not specially favourable, and perhaps ultimately inimical to their growth. The only terms, therefore, in which a *standard of purification* for a process or a *standard of permissible impurity* in an effluent can be expressed *are necessarily and solely chemical.* The function of bacteriological examination is in no way depreciated by this circumstance. If the

bacteria of sewage were constant in the sewage of all towns and at all epochs, and if the circumstances affecting their survival and metabolic activity were the same in all sewage or, if variant, they equally affected all the organisms essential to bacterial purification, the place for bacteriology in the matter would be confined to the determination of the extent to which effluents favoured or impeded the growth of undesirable organisms, in particular those which directly cause disease, and those which produce offensive organic substances.

This function it must have in any event, and in the present state of knowledge no general statement can be made in regard to the substantial constancy—that is, as to the constancy in particulars material to the purification processes—of the bacterial conditions to which I have referred. It remains, therefore, for bacteriology to determine the relation between the various organisms and the various chemical factors and physical conditions which occur in practice. The problem is one of extreme complexity, and its investigation is the more tantalizing by reason of the probability that many of the organisms normally found may be individually indifferent in the purification process. It is on this ground that I think the present object of such investigation should be rather the examination of these organisms in groups collected under such characters as those which I have selected than the individual identification of particular organisms. Such inquiry in any case has far more than academic interest. It may well turn out that in some cases artificial addition of bacteria may form a part of that process which in the particular circumstances is the most efficient. There remain, again, questions which experience at present has not gone far enough to settle; such, for instance, as the extent, if any, to which the first products of the bacterial energy are in stable or unstable equilibrium, and their liability, or freedom from liability, to become the subjects of secondary disintegrations, and to result in secondary degradation of the effluent. But whatever result such investigations may have, and essential as I regard them to placing the problem of sewage purification on a satisfactory basis, *it is in quantitative terms of the chemical products* which varying bacteria and varying conditions produce that the results of bacteriological investigation must be expressed before they pass over from the domain of experimental science into that of practical application.

In the absence of such data, it is impossible to define any standard either of percentage purification or of maximum permissible impurity which can be regarded as final or constant for all places. Several standards of permissible composition have been proposed; and perhaps it may be convenient if I re-state some of them. There is, first, that of the Rivers Pollution Commissioners:

	In Parts per 100,000.			
	Organic Carbon.	Organic Nitrogen.	Albuminoid Ammonia.	Oxygen Absorbed.
Rivers Pollution Commissioners ...	2·0	0·3	—	—
Derbyshire County Council	—	—	0·1	1·0

In addition, the Rivers Pollution Commissioners' standard requires that a certain degree of alkalinity or acidity is not to be exceeded, that the matter in suspension is not to exceed 3 parts per 100,000 of dry mineral matter, nor 1 part of dry organic matter, that there shall be no visible colour in a stratum 1 inch deep when viewed

in a white dish, nor any metals except calcium, magnesium, potassium, or sodium present to a greater extent than 2 parts per 100,000, and a limit is also set for free chlorine, for arsenic, and for sulphur as sulphuretted hydrogen or free sulphuric acid.

The other standard, suggested by Dr. Barwise, is of a much more practical nature, though it appears to me to be somewhat too severe, and is, in my opinion, rarely attained by any of the processes in common use. The Thames Conservancy, in the upper reaches of the river, recognises, as a "good effluent," any effluent which gives less than 0·2 part per million of albuminoid ammonia. I should be inclined to suggest the following standard as satisfactory for general use:

	Parts per 100,000.
Total suspended matter (not to exceed)	2·0
Albuminoid ammonia	0·2
Oxygen absorbed...	0·75
Total hardness	25·0
Nitrogen as nitrates (not to be less than)	0·75

The amount of nitrates should be insisted on, as showing that true purification has begun, and that there is a store of oxygen that could be drawn on, as a guarantee against possible putrefaction.

I base this standard on the fact that, on the examination of a large number of samples of effluents, I have found no sample which, falling within this standard, became putrefied on keeping either in closed or open vessels. For my own part, therefore, I should at present prefer this standard; but I put it forward with the reservation that any standard must at the present time be regarded as tentative, and be subject to, and likely to undergo, revision in, I hope, no distant future, when more exact data correlating the bacterial, physical, and chemical circumstances are available. In the meantime, however, I think that in this, as in so many other matters in which our profession is concerned, it would add to the authority of all of us, and conduce to the advantage of the public, if we could arrive at some agreement as to the standard which should, for the time being, be adopted in common.

Discussion.

Dr. Dupré said that he totally objected to any universally applicable standard being laid down in the case of sewage effluents. What was or was not permissible depended entirely upon where each effluent was to go to—whether, for instance, it was to be discharged into a comparatively large stream of water, or into a dry, or nearly dry, ditch. The Thames Conservancy had, he believed, several different standards. They would allow to be discharged below the intake of the waterworks an effluent which they would not allow to go into the river above the intakes. A very fair measure of the impurity present in a water or effluent might be obtained by determining the quantity of dissolved oxygen absorbed from the effluent. Pure water remained aerated when bottled up, but water containing sewage de-aerated itself. An effluent which did not appreciably de-aerate itself might be admitted anywhere without fear of putrefaction taking place. As a chemist, he always preferred to rely upon chemical tests, and to do without bacteriology if possible; and this measurement of the oxygen absorbed by the water itself was a fairly good substitute

for a bacteriological examination. Unfortunately, although the actual work could be carried out in a few minutes, the sample had to be allowed to stand for from five to ten days. He thought it of far more importance to agree to some methods of analysis than to lay down standards; he would particularly refer to the determination of the oxygen absorbed by permanganate. This was one of the most useful factors in a water analysis; but, unfortunately, chemists differed very greatly in their methods of arriving at it. Some followed the late Dr. Tidy, and used open flasks kept at the temperature of the laboratory, and hoped that an equal amount of dirt might fall into the flask containing the standard used for comparison, and into the experimental flask; others, like Dr. Rideal, placed their bottles on the top of the water-oven, others actually boiled their acidified solutions. It was, however, very desirable that all should agree to make the determination upon a definite plan. He believed that he had himself been the first to suggest the carrying out of the process in a closed bottle, and at a fixed temperature. In doing so, he had not had in view the question of chlorides being present; but it was found that the use of a closed vessel did away entirely with the difficulties arising from the presence of chlorine when an open flask was used. The determination, in fact, could be made in sea-water as easily as in ordinary drinking-water.

Dr. VOELCKER said that the importance of considering any particular effluent in relation to the water from which it was originally derived extended to other constituents besides the chlorine. For instance, in dealing with effluents from districts where the water was known to be unusually hard, the total hardness would have to be regarded in relation to that of the original water. It was important, also, to know the nature of the suspended matter, and whether it consisted of organic matter or merely of mineral matter. He had not noticed in the paper any reference to a question which he thought was a very important one, and which Dr. Dupré had alluded to, namely, the ratio of the volume of the effluent to that of the stream into which it flowed.

Dr. RIDEAL quoted, as an instance of the unreliability of standards, a case which had been referred to in a paper read by him before the Society of Arts, of a solution of putrid meat extract, diluted with water in the proportion of 1 to 6,000. The liquid was very putrid, smelling strongly of sewage, and was no doubt also a toxic solution containing ptomaines; but it would nevertheless have passed any ordinary standard in regard to free and albuminoid ammonia, oxygen absorbed, etc. What, he thought, was to be aimed at was not so much a fixed standard as a ratio, showing what had become of the nitrogen, and how it had been altered. In the original sewage the nitrogen would be entirely in the organic state. The action of bacteria resulted in the breaking down of this organic nitrogen with the production of free ammonia, followed by the formation of nitrites and nitrates, until finally the nitrogen became entirely oxidized. The total nitrogen in a sewage effluent, therefore, was to be looked upon as existing in four distinct forms, namely, organic nitrogen, free ammonia, nitrous nitrogen, and nitric nitrogen; and it was the ratio of these four different kinds of nitrogen to one another which indicated whether an effluent was satisfactory or not. If the ratio between the first two and the second two was such that the balance of oxygen in the nitrites and nitrates was more than sufficient to oxidize the nitrogen

not yet oxidized, the liquid could not undergo any putrefactive change likely to cause a nuisance. He therefore agreed with Mr. Moor in the importance of ascertaining that the nitric nitrogen was not below a certain amount, but contended that the amount was determined by the amount of the unaltered nitrogen present. He had found the loss on ignition to be a very unsatisfactory figure, yielding no information as to the quantity of organic matter present in sewage after treatment. In some cases it would even increase, instead of diminish, after the sewage had undergone a process supposed to destroy organic matter.

Mr. CHAPMAN said that in his experience it was usually impossible to derive any satisfactory information from the loss on ignition. In very many cases (more especially in impure waters) the loss due to decomposition experienced by the mineral matter, and to the expulsion of combined water, far overbalanced any loss that might be due to the combustion of organic matter. Dr. Rideal had apparently assumed that a reaction would occur between the nitric and nitrous acid, and the ammonia present in a sewage effluent; but he (Mr. Chapman) did not think there was sufficient evidence to show that such a reaction would take place in the dilute solutions in which these substances were found in effluents. It was not always safe to assume that changes which took place in concentrated solutions also took place in very weak solutions.

Mr. CASSAL said it was not possible to lay down rigid standards in matters of this kind. The question was really one that involved the getting of some figures by which the expert might be guided, and he thought that Mr. Moor's object was rather to put before the Society some figures which, upon broad lines, would be of assistance in arriving at conclusions, than to suggest the laying down of any rigid standards. It was quite plain that such matters must be governed by the special circumstances of each particular case. It was dangerous to speak of good, bad, and medium effluents. The object of the Local Government Board in insisting upon the treatment of sewage by passing it through land had obviously been, or ought to have been, the absolute purification of the sewage from objectionable organic matter by filtration through the soil; a purification carried to such an extent that the resulting effluent should be no fouler than the stream into which it was to flow. Theoretically, at any rate, it ought to be assumed that there should not be introduced into any stream or river a liquid which contained in a notable degree a larger quantity of putrescible organic matter than was present in the stream itself. If the stream itself was polluted, the question of special circumstances came in very strongly, and the conclusions of the engineer, as well as those of the chemist, had to be applied in order to determine whether there was any possibility of an increase in the pollution of the stream by the introduction of any given effluent. Apart from this, the aim of the sanitarian should be the introduction into any stream or river of perfectly purified or demonstrably innocuous effluents. He, too, was of opinion that the ignition of water, or sewage "residues," while it was a valuable qualitative test, was not a reliable quantitative one, except when employed in connection with the same set of water, sewages or effluents, as a means of comparison merely among the samples themselves.

The PRESIDENT said that the subject of standards was a most difficult and, indeed, a dangerous one to deal with. The real question in any given case was

probably how far the effluent approximated to the best possible effluent that could be reasonably expected, having regard to local circumstances and to the means which it was reasonably possible to employ. The great absurdity attaching to standards under some conditions had once been shown by a well-known manufacturer at a meeting of the Society of Chemical Industry, at the time when it was suggested that the standards recommended by the Rivers Pollution Commission should be legalised. That gentleman observed that he daily ejected from his works an effluent which in very nearly every particular transgressed the limits laid down, the effluent in question being, however, merely the water of the river on which his factory was situated, which water was pumped into the works for use in cooling the condensers, and afterwards returned in its original condition to the river. The river, however, would be held to be thereby polluted, if the suggested standard were legalised. While, however, it was exceedingly difficult to lay down general standards, it was very desirable that there should, if possible, be some settled means of making the different determinations involved in analyses of this kind. It seemed, for instance, particularly important to decide and agree whether, if an effluent contained suspended matter, it should be shaken up and analysed as a whole, including the suspended matter, or whether it should be filtered, or whether it should be allowed to settle; and also whether, if it was filtered, a close paper or a loose one should be used. Such considerations as these gravely affected the determinations of oxygen absorbed and albuminoid ammonia.

Mr. W. J. DIBDIN desired to compliment the author upon the excellent paper which he had presented to the Society. The question of standards of quality for sewage effluents was perhaps one of the most difficult of all those raised in connection with sanitary problems. It had been suggested that the quality of the effluent should be equal to that of the stream into which it is to be turned. This was at once met by the consideration of the case of an effluent discharged from a sewage farm even in the very best working condition, the outfall from which was on the banks of a stream which had but a few minutes before sprung from, say, the outcrop of the chalk. It would be practically impossible to comply with the prescription, and an exception would have to be made. If one exception, why not two or three? He had long since adopted in his own mind a physiological standard, viz., that the quality of an effluent should be such that fish could live healthily in it. Such an effluent is not a fanciful one, nor is there any difficulty in obtaining it by the employment of suitable means, and these, fortunately, are most economical. Such a definition involves necessarily the absence of poisons and the presence of oxygen. This raises the point as to the quantity of nitrates which should be present, as, according to Mr. Moor, these present a store of oxygen that could be drawn on. This is so; but the statement overlooks the important fact that when water is freely in the presence of air, such as in a stream, etc., it acts like a sponge, greedily absorbing oxygen from the atmosphere as fast as it yields it up to the organisms feeding on the organic matter, so that at some point, determined by the rate at which these organisms require it, a balance is arrived at. If the aeration is kept down very low by the rapidity of the life processes, this absorption of atmospheric oxygen is very rapid, varying in inverse ratio to the degree of aeration. From this consideration it will be evident that, valuable as is the indication afforded by the presence of nitrates, these must not be looked upon solely as a

store of oxygen, and still less as the sole store of that substance for effecting the ultimate purification of the sewage matters. With regard to the nitrites in effluents being only present after these have been kept for some days in bottles, he was afraid that he could not agree with the author of the paper. In the course of a series of special experiments, conducted on the works, Mr. Thudichum found at Exeter that nitrites were present in every sample tested direct as it came from the fine coke-breeze filters. He was in full agreement with the author's suggestion that the lower the quantity of albuminoid ammonia the better, but, unfortunately, this point did not much help the question of standards. With regard to the temperature of the sewage rising in some bacterial processes, this was unquestionably the fact, and was comparable to the familiar instance of the garden hot-bed. In some bacteria beds under his (Mr. Dibdin's) direction the temperature had risen as high as 80° F. With reference to the loss on ignition being an important point, he could not agree with this in all cases. For instance, where a large quantity of mineral salts were sent into the sewage, the loss due to water of crystallization, etc., would often be so great as to swamp all that due to the organic matter, and thus no factor of any value at all from this point of view was obtainable. The value of the relation of the results of analyses must, for the present, at least in the majority of cases, be based upon the personal equation, in which large experience and knowledge of the local conditions as to necessities and possibilities were all involved.

Mr. Moor said that he very much appreciated the sympathetic criticism to which his remarks had been submitted, and, while opinions seemed to vary on points of detail, he could not help thinking that even the variety of opinion which had been expressed emphasized the desirability of having some set of figures on which an effluent could at least be condemned. He had endeavoured very clearly to indicate that the particular set which he had suggested was by no means put forward either as a final standard or as an ideal effluent. Perhaps his meaning would have been made clearer if he had described these figures, as he had in fact intended them, as constituting, not the standard for an effluent which could permanently or in all circumstances be adopted, but the maximum of impurity which should in any circumstances be allowed. By the adoption of this maximum, he in no way intended to suggest that such effluent would in all cases be permissible; for example, he would regard it as quite out of the question for an effluent to be discharged in any quantity above a water company's intake. In making this remark, he desired to add, for fear of misunderstanding, that, in his judgment, no chemical criteria could ever warrant the safety of an effluent above an intake; but that, as the danger would to some extent vary inversely with the chemical purity, he would insist on a much higher standard for effluents supplied to sewage-drinking communities than that which he had discussed in this paper. None of the criticism which had been offered appeared to him to conflict with the adoption of these figures for this purpose, with the single reservation pointed out by Dr. Voelcker—that the hardness of effluents should be fixed in some relation to that of the water-supply. His purpose in including this figure was of course to prevent the undue drugging of the water with chemicals employed in processes of treatment; and he suggested, therefore, as an emendation of the absolute figure which he had at first suggested, the provision that

total hardness of effluent should not exceed that of the water-supply by more than 25 parts per 100,000. He was in entire agreement with Mr. Cassal that at the present time no data existed warranting the description of an effluent as good or indifferent; but he still thought that there would be considerable advantage in having some figures by which in need it could be described as bad, as it followed logically, from what the President had rightly observed, such figures must represent the best effluent which could in all circumstances be attained. He did not understand the President to suggest that the figures which he (the speaker) had proposed were such as were likely to occur in a natural river; and if by artificial pollution a river had been so contaminated as to fall short of his modest requirements, he thought there would be every possible advantage in preventing ingenious and energetic persons, such as the gentleman to whom the President referred, from using such river for any purpose until they had gone up stream and compelled the persons polluting the river to leave off. Taking the determinations which he had suggested individually, he had no hesitation in saying in reply to the President's question that analysis must take impartial account of everything which appeared in the sewage; and, feeling as he did that suspended matter had no right in an effluent to any extent exceeding that which he had suggested, he was convinced that the only discrimination allowed to the analyst was the careful collection of an average sample, which then would be shaken up and analysed as a whole. So far as mineral matter was concerned, his experience was that it settled so much more rapidly than animal and vegetable matter, that the reservation suggested by Dr. Voelcker was not likely to be needed in practice, and he, personally, had met with no case in which it would have modified his proposed criterion. It was to be observed also, from the bacteriological standpoint, that suspended matter was usually far richer in organisms than the liquid conveying it; and as it certainly could be prevented by reasonable measures, he thought it needless to make any allowance for cases in which a substantial part of it might be mineral.

So far as the albuminoid ammonia was concerned, no question appeared to arise as to the figure which he had suggested being too high. He personally preferred the oxygen-absorbed determination to that proposed by Dr. Dupré, because of its greater rapidity; but having regard to the difficulty of attacking all the organic matter in sewage by permanganate, especially where there was much suspended matter, he thought it might be worth considering whether one or other of the higher temperature processes would not be preferable for routine sewage examination to the ordinary Tidy modification of the Forchammer process, which was usually employed. He should have explained that in suggesting loss on ignition as a valuable characteristic of the same order as "oxygen absorbed," he had in mind the successive examinations of the same sewage, such as would occur in the examination of a process; and he quite agreed with Mr. Dibdin that it would not serve as a factor for comparison between sewages of different origins, and for this reason he had not proposed it as part of his suggested criterion. So far as nitrites were concerned, he was bound to say that while he had repeatedly found them in samples of which the examination had been delayed for a short time, he had never found them in freshly-examined samples. He recognised with Mr. Dibdin that there were other sources of oxygen in water than the nitrates,

but seeing that his (the speaker's) figure was only proposed as a minimum, he did not think that this fact would warrant the reduction of the figure of nitrates which should be required. The utility of this factor was evident from Dr. Rideal's meat-extract, which certainly would have been condemned for its deficiency in this respect, and with equal certainty, had it passed through any sewage process capable of bringing it up to the standard in this particular, would have ceased to be offensive. In conclusion, he would reiterate that the whole, if any, of the figures which he had proposed was not to constitute an ideal or permanent criterion, and in that sense perhaps the word "standard" would be as inapplicable to these as to other figures which had been proposed for the same purpose. His figures would unquestionably be superseded by others more severe when data were available for safely defining them. They might even now be supplemented, if it was thought desirable, by Mr. Dibdin's test of the survival of fish, or by Dr. Dupré's requirement of permanent aeration. But the speakers had not suggested, nor was he aware of any sufficient evidence at present available, to justify exclusive reliance on either of these tests; and as, therefore, a chemical criterion was undoubtedly necessary, he appealed to the Society to consider whether it was not for the public interest and for that of the profession that an agreement should be come to at least as to the figures on which all analysts would condemn an effluent.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

A New Method of sophisticating Coffee. G. Wirtz. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 248.)—The author states that coffee is largely sophisticated in Hamburg, Bremen, Antwerp, and Rotterdam, as well as in the places of origin, by the process of washing, coloring, and drying off in centrifugal machines with sawdust, with the result that the furrows of the berries become filled with wood powder, making them a fine white and enhancing the market value of the produce. H. H. B. S.

Paprika (Cayenne) as a Substitute for Alcohol. Kellermann. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 247.)—The attention of the author was drawn to a description of spirit which had a sharp taste, and produced a greater sensation of warmth than other competing spirits, though containing less alcohol. The residue left on distilling was found to produce an intense and lasting burning sensation when applied to the mucous membrane of the lips, exactly similar to that produced by "paprika." The addition of an alcoholic extract of "paprika" to common spirits produced a spirit possessed of the same peculiarities. H. H. B. S.

A New Method for the Valuation of Amyl Nitrite and Spirit of Nitrous Ether. **C. E. Smith.** (*Amer. Jour. Pharm.*, 1898, lxx., 273-285).—This is a volumetric process based on the reaction between nitrous and chloric acids:

$$3HNO_2 + HClO_3 = 3HNO_3 + HCl.$$

Spirit of Nitrous Ether.—The following are successively placed in a 100 c.c. flask provided with a loosely-fitting stopper: Ten c.c. of water, 5 c.c. of a cold saturated solution of potassium chlorate, 5 c.c. of the spirit to be tested, and 5 c.c. of 10 per cent. nitric acid. After shaking at intervals for thirty minutes, 10 c.c. of decinormal silver nitrate are added, the flask shaken for a moment, and the excess of silver titrated as rapidly as possible with decinormal potassium thiocyanate, a few drops of a solution of ferrous ammonium sulphate being used as indicator. The end-point of the titration is reached when, after *momentary* shaking, the liquid remains faintly red throughout.

Each c.c. of silver nitrate consumed corresponds to 0·0225 gramme of ethyl nitrite, and if the specific gravity of the sample be taken as 0·84, which is usually approximately correct, the calculation can be shortened by multiplying the number of c.c. by 0·536.

Concentrated nitrous ether may be assayed by diluting with alcohol in definite proportions, and proceeding as above.

The results are invariably higher than those obtained by the usual gaso-volumetric method, but from the results of comparative experiments the author considers the new process the more accurate of the two.

The following results were obtained in the analysis of commercial samples, of which the last was a sample of concentrated nitrous ether, stated to be 90 per cent. ethyl nitrite. It was tested after dilution to 4 per cent.

	Per Cent. Ethyl Nitrite. U.S.P. Method.	Per Cent. Ethyl Nitrite. Chlorate Method.	Per Cent. of Free Acid.	Aldehyde Test.
1.	3·66; 3·70	4·06; 4·01	0·14	Faintly yellow.
2.	4·84; 4·88	5·30; 5·30	0·11	,, ,,
3.	4·28; 4·31	4·58; 4·60	0·45	Dark.
4.	3·95; 4·00	4·38; 4·44	0·15	Straw.
5.	4·35; 4·32	4·81; 4·84	0·31	Dark.
6.	85·50; 85·90	92·60; 92·00	0·46	Straw.

The acid determinations were made with normal soda, without dilution with water. Addition of water or titration with decinormal soda gave considerably higher results, probably through saponification of the esters. All of the samples answered the requirements of the Pharmacopœia (U.S.A.) test for aldehydes, which prescribes that the colour shall not be decidedly brown after twelve hours' contact with alkali.

Amyl Nitrite.—A 100 c.c. flask is partially filled with alcohol and weighed. Five to six grammes of the amyl nitrite are then added, the flask again weighed, and the liquid made up to the mark with alcohol and well shaken. The determination is carried out in the same way as described for nitrous ether, except that double quantities of the reagents and of the alcoholic solution of amyl nitrite are used. One c.c. of decinormal silver nitrate corresponds to 0·0351 gramme of amyl nitrite.

The following table gives the results obtained with commercial samples:

	Per Cent. Amyl Nitrite. U.S.P. Method.	Per Cent. Amyl Nitrite. Chlorate Method.	Per Cent. of Free Acid.	Aldehyde Test.
1.	77·20; 77·0	87·0; 87·4	0·6	Dark straw colour.
2.	76·0; 76·4	86·7; 86·2	0·67	Brownish yellow.
3.	17·3; 18·8	21·0; 18·9	0·76	Deep yellow.
4.	82·7; 83·5	93·9; 93·4	1·36	Dark straw colour.
5.	79·0; 78·4	85·9; 85·3	1·12	Deep yellow.

Of these, No. 3 was from a bottle with an old and defective cork which had been badly attacked by the liquid; Nos. 4 and 5 exceeded the Pharmacopœia limit of free acid, which is 1·08 per cent. as nitrous acid; and none of them were fully up to the standard required by the aldehyde test, which prescribes that on shaking equal volumes of amyl nitrite and normal potassium hydroxide the aqueous layer shall not be more than pale yellow.

The author advises that a blank determination should be made in the assay and an allowance made for the impurities, since potassium chlorate and nitric acid often contain traces of chloride, and nitric acid lower oxides of nitrogen, both of which would affect the results. C. A. M.

Detection of Salicylic Acid in Comestibles. F. A. Genth. (*J. Franklin Inst.*, 1898, cxlv., 228; through *Chem. Zeit. Rep.*, 1898, 97.)—The author considers Krause's distillation process the best for the detection of salicylic acid in articles of food. The substance is rubbed down to a cream with phosphoric acid, water being added if necessary. After a time, the mass is squeezed through a cloth, and 50 or 75 c.c. of the liquid are submitted to distillation, every 5 c.c. of the distillate being tested with ferric chloride. The salicylic acid passes over with the steam, most of it being recovered towards the end of the operation. The methyl-ester reaction is not suited for detecting small quantities of the antiseptic; but by this process Genth has discovered the presence of salicylic acid in various preserves which nominally did not contain it. F. H. L.

The Examination of Methyl Salicylate. Adrian. (*Journ. Pharm. Chim.*, 1898, vii., 122-124.)—Physiological experiments having demonstrated the superiority of methyl salicylate over the natural oil of winter-green, it is important to be able to distinguish between the two, although on account of its higher price the latter is hardly likely to be fraudulently substituted for the artificial product.

The following table gives the comparative results of the fractional distillation of samples of undoubted purity:

Methyl Salicylate.		Density at 15° C.	Oil of Winter-Green.		Density at 15° C.
A little water (5 grammes) distilled over below 220°.			A little water (5 grammes) distilled over below 220°.		
	Grammes.			Grammes.	
Distilled below 220° (nearly all at 219°) ...	110	1·1785			
Between 220° and 222°	105	1·178	Between 220° and 222°	615	1·185
,, 222° and 223°	155	1·179	,, 222° and 223°	190	
,, 223° and 225°	350	1·180	,, 223° and 225°	85	
,, 225° and 230°	185		,, 225° and 230°	50	
Residue	90		Residue	55	
Total ...	1000		Total ...	1000	

The density and boiling-point are valuable tests, and will detect the presence of free methyl alcohol or of ethyl alcohol fraudulently added. The addition of a fixed oil would lower the specific gravity, and a residue would be left on distillation from which, on heating more strongly, acrolein vapours would be liberated.

Methyl salicylate can be distinguished from oil of winter-green by its behaviour with sulphuric acid. On mixing 5 c.c. of methyl salicylate or of one of the distilled fractions (previously well dried) with an equal volume of sulphuric acid, there is no rise of temperature, but the ester assumes a faint yellow colour, with the exception of the fraction distilling below 220°, which does not give the coloration.

On treating the natural product in the same manner, and especially the fraction distilling between 220° and 222°, which contains the terpene, gaultherylene, there is an immediate rose coloration, changing to red and finally to dark brown, and there is also a considerable evolution of heat. C. A. M.

Oil of Sassafras. C. H. La Wall and R. C. Pursel. (*Amer. Jour. Pharm.*, 1898, lxx., 340-342.)—This oil, which is largely employed by soap-manufacturers, is very liable to adulteration. As the boiling-point shows considerable variation in pure specimens, the chief points relied upon in judging of the quality of a sample are its specific gravity, general appearance, and odour. Safrol was formerly used as an adulterant, but its price is now higher than that of the oil. It constitutes normally about nine-tenths of the weight of the oil, and has a specific gravity of 1·108, whilst the specific gravity of sassafras oil varies from 1·07 to 1·09. Oil which has a lower gravity than the lower limit is regarded with suspicion, as it might indicate adulteration with the fractionated camphor oil which is used for that purpose. In cold weather crystals of safrol are deposited, and it may often happen that the upper, middle, and lower portions of the oil are of different gravities, and in such cases the only way to insure a homogeneous mixture is to pour out part of the oil before stirring, and then to agitate very vigorously. The authors refer to an instance in which, after apparently well mixing the whole bulk and leaving no crystals at the bottom, the gravity was found to be 1·055, but after more thorough admixture was 1·07.

The following table gives the maximum, minimum, and mean specific gravity of all the samples examined by the authors from 1896 to June 1, 1898. They represent an aggregate of 10,000 lb. as received from the distiller.

	Maximum.	Minimum.	Mean.
1896	1·0840	1·0500	1·0654
1897	1·0850	1·0610	1·0736
1898	1·0830	1·0450	1·0713

The colour of the pure oil varies from deep yellow to nearly colorless. The artificial oil closely resembles the natural product, and an admixture is not readily detected. C. A. M.

Croton Oil. Javillier. (*Journ. Pharm. Chim.*, 1898, vii., 524-527.)—It is stated that the variations in the constants of this oil, as determined by different observers, are largely due to the method by which the oil was obtained. The author prepared three samples, the first by simple expression, the second by lixiviation with ether, and the third by digestion at 75° C. with 95 per cent. alcohol, the first two methods being those prescribed by the French Codex of 1884. In each case a different yield and a different-coloured product was obtained, *viz.*, (1) 12·5 per cent. of a pale oil; (2) 38 per cent. of a light-brown oil; and (3) 12 per cent. of a very dark-brown oil.

The difference in their physical and chemical properties is shown in the following table:

Solubility in Alcohol.	Expressed Oil.	Oil extracted with Ether.	Oil extracted with Alcohol.
(1 vol. of oil + 2 vol. absolute alcohol.)	Soluble at 75° C.	Soluble at 75°.	Soluble in the cold.
Solidification temperature ...	− 7° C.	− 7° C.	− 8° C.
Iodine value (Hübl)	109	108	91·2
Saponification value	192·9	194·5	260·6
Acid value	27·3	30·9	60·1

The acid value was determined by dissolving the oil in ether and titrating directly with decinormal alcoholic potash. It was found that Henrique's method of cold saponification was not easily effected with croton oil.

The commercial oil is often prepared by the methods given in the Codex of 1837 and 1866, *viz.*, expression followed by digestion with 80 per cent. alcohol. Its iodine value is generally about 102, and the saponification of a sample examined by the author was 205·6. C. A. M.

The Examination of Theobromine. M. François. (*Journ. Pharm. Chim.*, 1898, vii., 521-523.)—The most probable adulterant of theobromine (which has recently been employed in therapeutics) is caffeine, which is considerably cheaper. The author describes the following tests of the purity of the drug:

1. On adding 10 c.c. of a 10 per cent. solution of silver nitrate to a solution made by dissolving 0·1 gramme of theobromine in a hot mixture of 1 c.c. of nitric acid and 2 c.c. of water, a turbidity occurs, which on warming disappears. On cooling, a mass of needle-shaped crystals is deposited.

2. A solution is prepared by dissolving 0·1 gramme of theobromine in a mixture of 2 c.c. of water and 1 c.c. of hydrochloric acid. Ten c.c. of bromine water are added, the beaker and its contents weighed, the excess of bromine expelled by heat, which is continued until the liquid becomes practically colorless, and the original weight made up with distilled water. This solution when cold stains the skin red. On adding to 2 c.c. of the liquid 1 drop of a 5 per cent. solution of ferrous sulphate and 2 or 3 drops of ammonia solution, an intense indigo-blue coloration is obtained. (A reaction also given by caffeine.)

3. A solution of 0·1 gramme of theobromine in a mixture of 2 c.c. of water and 1 c.c. of hydrochloric acid, mixed with 10 c.c. of decinormal iodine solution (I, 12·7 grammes; KI, 20 grammes; water, 1 litre), gives a dense black precipitate. This is separated by decantation, and dissolved in a 10 per cent. aqueous solution of potassium iodide at 80° C. On cooling, greenish-black crystalline needles of theobromine tetra-iodide are deposited.

Theobromine should leave no residue on ignition, and should melt at 338° to 340° C. The determination of its solubility in alcohol should detect caffeine and other organic substances (alkaloids, glucosides, etc.). Ten c.c. of 95 per cent. alcohol, saturated with theobromine at 21° C., leaves on evaporation a residue of 0·0045 gramme, whilst 10 c.c. of the same alcohol, saturated with caffeine, leaves 0·0930 gramme. Hence theobromine, containing 5 per cent. of caffeine, treated with alcohol, kept at 21° C. for forty-eight hours would give a solution containing in 10 c.c. 0·0290 gramme instead of 0·0045 gramme. C. A. M.

The Assay of Belladonna Plasters. C. E. Smith. (*Amer. Journ. Pharm.*, 1898, lxx., 182-189.)—The belladonna plasters of the American market are nearly always prepared with a base containing rubber and various resins. In their preparation the rhizome of the *Scopolia carniolica* is often used instead of the *Atropa belladonna*, but as the alkaloids are practically the same in both plants, and are present in more uniform quantity in the former, the author considers that there is some excuse for the substitution.

The method of assay which he has found the most accurate and reliable is as follows:

If the sample is of about the strength of the U.S.P. standard, one plaster (about 8 grammes) is taken, or if weaker, proportionately more. The part of the cloth on which the mass is spread is weighed, cut into strips, and stirred up with 50 c.c. of chloroform and 10 drops of 10 per cent. ammonia-water, until the mass is completely dissolved off the cloth. The chloroform mixture is decanted, the rubber precipitated by the addition of 40 c.c. of 91 per cent. alcohol, and the supernatant liquid decanted into a separatory funnel. The cloth left in the first beaker is washed with 25 c.c. of chloroform and 5 drops of ammonia-water, and the washings decanted into the second beaker, where they redissolve the precipitated rubber. The solution is well stirred, the rubber again precipitated by the addition of 20 c.c. of alcohol, and the supernatant liquid added to that in the separatory funnel. This process is repeated until the whole of the mass is removed from the cloth and the beaker.

The combined chloroform-alcohol solutions in the separatory funnel are mixed with 20 c.c. of water containing 2 c.c. of hydrochloric or sulphuric acid and shaken gently for five minutes. The chloroform solution is then drawn off into another funnel, together with any solid matter that may have collected at the line of contact of the two layers, while the acid solution at the top, which contains most of the alkaloid, is transferred to a third separatory funnel. The extraction of the chloroform-alcohol solution with acidulated water is repeated three or four times, or so long as any considerable amount of solid matter collects at the juncture of the liquids.

The combined acid solutions are made alkaline with ammonia, and the alkaloid gently shaken out with successive portions of 20, 10, and 10 c.c. of chloroform. (Violent agitation produces an emulsion.) The combined chloroform extracts are washed with water and transferred to a flask, where the chloroform is evaporated on a water-bath.

The alkaloidal residue is shaken with 4 c.c. of N/20 acid until all the alkaloid is dissolved. Fifty c.c. of water are then added, followed by 0·5 c.c. of a 1 per cent. alcohol solution of hæmatoxylin, and N/20 alkali is run in until the colour of the liquid changes to dull red. The number of c.c. used is subtracted from 4, and the remainder multiplied by 0·0145 (the N/20 factor for atropine and its isomers), and by 100, and the product divided by the net weight.

For example, a plaster weighing 12·25 grammes with the cloth, and the cloth weighing 3·55 grammes, required 1·58 c.c. of N/20 alkali to neutralize the excess of acid.

$$\frac{(4 - 1{\cdot}58) \times 0{\cdot}0145 \times 100}{12{\cdot}25 - 3{\cdot}55} = 0{\cdot}404 \text{ per cent. of alkaloid.}$$

The results of the analyses of eleven samples comprising the products of six manufacturers, including all the prominent American makers, were:

	Per cent. of Alkaloid in Mass.	Weight of Mass in one Plaster. Grammes.
1.	0·571 to 0·594	8·55
2.	0·403 ,, 0·416	8·7
3.	0·509 0·497	—
4.	0·112 0·108	8·65
5.	0·103 0·110	—
6.	0·060 0·058	8·2
7.	0·084 0·081	7·35
8.	0·125 0·116	3·25
9.	0·098 0·101	8·35
10.	0·042 0·047	5·7
11.	0·093 0.096	—

All the samples responded to Vitali's test for solanaceous alkaloids except No. 11, a foreign sample which contained some interfering impurities. Judging by the presence of chlorophyll, No. 2 and No. 11 were prepared from the leaf extract. Only three samples conformed to the U.S.P. standard of strength, all the remainder being much below it. C. A. M.

ORGANIC ANALYSIS.

A New Reaction of Tertiary Alcohols. G. Deniges. (*Comptes Rend.*, 1898, cxxvi., 1277-1279.)—The test here described is applicable to the detection of all compounds which readily yield hydrocarbons of the ethylene series, but especially to tertiary alcohols. The reagent consists of mercuric oxide 50 grammes, sulphuric acid 200 c.c., and water 1000 c.c. On warming two or three drops of a tertiary alcohol with a few c.c. of this solution, a yellow precipitate is rapidly produced, the tint varying with the particular alcohol tested.

In the case of butylic alcohol the yellow compound, when washed and dried in the dark over sulphuric acid, has a composition corresponding to the formula,

$$\left(SO_4\langle{}^{Hg}_{Hg}\rangle O\right)_3 \cdot C_4H_3,$$

which is also the formula for the substance yielded by dissymetric dimethyl ethylene, the corresponding olefiant hydrocarbon. It is soluble in hydrochloric acid with effervescence yielding butylene and mercuric chloride. On boiling the precipitate in its mother liquid for ten minutes, the colour disappears, and finally mercurous sulphate is produced with oxidation of the butylene residue. The test is very sensitive, and is capable of detecting 0·001 gramme of the alcohol.

Tertiary amylic alcohol mixed with three to four times its volume of the reagent and gently warmed, gives a yellow precipitate identical with that yielded by the corresponding ethenic hydrocarbon. On boiling, it is immediately decomposed, giving mercurous sulphate, which is rapidly reduced to metallic mercury.

There is a characteristic difference in the behaviour of pental and tertiary amylic alcohol with the reagent. The former gives an immediate yellow coloration in the cold, followed by the gradual formation of a precipitate of which there is an abundant deposit after ten minutes. Tertiary amylic alcohol scarcely shows any alteration in the cold, though on warming it gives the three stages of the reaction described above. When a drop of the liquid under examination is added to 2 c.c. of the boiling reagent a yellow precipitate is obtained which does not alter on standing in the case of pental, whereas with tertiary amylic alcohol the precipitate becomes white and crystalline and finally gray.

The other tertiary alcohols give analogous compounds with the reagent, always provided they are capable of yielding hydrocarbons of the ethylene series on dehydration. Primary and secondary alcohols do not form these compounds. Isopropylic alcohol, however, which is readily dehydrated with the formation of propylene, gives a precipitate with mercuric sulphate, but with much less readiness than the tertiary alcohols. The esters of tertiary alcohols also give a yellow precipitate with the reagent, and the test is very characteristic in the case of the tertiary amylic nitrite employed in medicine. C. A. M.

Preparation of Soluble Starch. A. Wroblewski. (*Chem. Zeit.*, 1898, xxii., 375.)—20 grammes of rice starch are rubbed down with 100 c.c. of cold water, poured into a 2-litre flask, 1 litre of a boiling 0·5 per cent. solution of caustic potash added quickly, and the whole boiled for 1½ or 2 hours under a reflux condenser till

the liquid becomes thin and pale yellow. The solution is filtered, neutralized with dilute acetic acid (to remove the free alkali and so facilitate the subsequent washing), and precipitated with an equal volume of 95 per cent. alcohol. The starch is filtered off, washed successively with 50 per cent., 95 per cent., and 100 per cent. alcohol, then with ether, and finally dried *in vacuo*. The substance thus obtained is a snow-white powder containing 0·4 to 0·6 per cent. of ash, soluble in about 33 parts of water, and insoluble in cold 35 per cent. or hot 45 per cent. spirit; it does not reduce Fehling's solution, and gives a pure blue colour with iodine. If a very pure material is required, the first product may be dissolved in water and precipitated with alcohol three or four times; it then retains but 0·15 or 0·18 per cent. of ash, while the yield is about 70 per cent.

The solubility of soluble starch in dilute spirit is largely dependent upon the amount of inorganic salts present; and in the same manner with dextrin, etc., if the liquids are too pure, it may be necessary to introduce a small quantity of potassium acetate before precipitation can be effected. F. H. L.

The Solubility of Pentosans in the Reagents employed in the Estimation of Starch. W. H. Krug and H. W. Wiley. (*Jour. Amer. Chem. Soc.*, 1898, xx., 266-268.)—In the determination of starch in a cereal or fodder by digesting the substance at a high pressure with water containing some organic acid, the action of the latter on the pentosans and hemi-celluloses results in the formation of reducing substances. The authors have determined the amount of the pentosans dissolved in this way with the following results:

1. Solubility of the pentosans by digesting for two and a half hours at three and a half atmospheres with 30 c.c. of water and 25 c.c. of 1 per cent. lactic acid.

Substance.	Per Cent. of Pentosans in Substance.	Pentosans Dissolved. In Per Cent. of Substance.	Pentosans Dissolved. In Per Cent. of Pentosans.
Wheat No. 1	5·80	4·63	79·83
Wheat No. 2	5·17	4·66	90·13

2. Solubility of pentosans by digesting for two and a half hours at three and a half atmospheres, with 55 c.c. of water and 0·5 gramme of salicylic acid.

Substance.	Per Cent. of Pentosans in Substance.	Pentosans Dissolved. In Per Cent. of Substance.	Pentosans Dissolved. In Per Cent. of Pentosans.
Wheat No. 1	5·80	4·54	78·27
Wheat No. 2	5·17	4·08	78·91

J. König (*Landwirthsch. Ver. Stat.*, xlviii., 81) states that diastase also acts as a solvent for pentosans and hemicelluloses, and gives figures to show that from 15 to 44 per cent. of the total amount of those substances present pass into solution.

The authors have made a number of starch determinations in various cereals by means of malt-extract and taka-diastase solution, from the results of which they conclude that diastase has no solvent action on the pentosans, and that this method of determining starch is an exact and reliable one. C. A. M.

A Comparison of the Standard Methods for the Estimation of Starch. H. W. Wiley and W. H. Krug. (*Journ. Amer. Chem. Soc.*, 1898, xx., 258-266.)—Referring to Stone's modified method (ANALYST, xx., 19), the authors show that a digestion of the starch with diastase for 2½ hours at 50° C., instead of for one hour at 60° C., gives a result about 1 per cent. higher. Further, by grinding the sample to a much finer powder than Stone prescribes, a considerably higher result is obtained. The comparative mean results obtained with a sample of wheat, analysed by (1) this method, (2) by Reinke's method (digestion under pressure with water containing lactic acid, to prevent the decomposition of sugars formed in the hydrolysis), and (3) by a method differing from Reinke's, by the substitution of salicylic acid for lactic acid were (1) 62·46, (2) 62·32, and (3) 63·09 per cent. In another paper the authors show that by the two latter methods considerable quantities of the pentosans present are also dissolved (*cf.* preceding Abstract). Of the two, the salicylic acid is preferable, since much less caramelization takes place. When it is employed, the amount of starch may be very approximately determined by diminishing the apparent percentage by 1·25. If greater exactness is required, the pentosans should be determined and the percentage divided by three and subtracted from the apparent percentage of starch.

From the results of experiments with the various polarimetric methods, the authors conclude that none of them can be relied upon to give accurate results.

They find Lindet's method (solution of the proteid envelope of the starch cell by means of pepsin and weighing the starch directly, ANALYST, xxii., 20) is more tedious than the common processes, and not so accurate. Small particles of substances other than starch pass through the sieve cloth and are weighed with the starch. On the other hand, a portion of the starch remains attached to the filter, and these two errors may often compensate one another, and an approximately correct result be obtained. The following are some of the figures given in illustration of this :

	LINDET METHOD.			DETERMINATION AFTER CONVERSION INTO DEXTROSE.			
CEREAL.	Starch per cent.	Residue per cent.	Total per cent.	Starch per cent.	Residue per cent.	Total per cent.	Fibre in Starch per cent.
Oats	44·31	0·00	44·31	43·73	0·00	43·73	0·58
Barley	71·41	0·97	72·38	66·47	0·97	67·44	4·94
Rye	61·24	0·79	62·03	58·18	0·79	58·97	3·06
Wheat	66 05	0·60	66·65	60·11	0·60	60·71	5·94

The percentage of starch in the same cereals as determined by the salicylic acid method and the diastase method were :

	Salicylic Acid Method.	Diastase Method.
Oats	46·78	45·05
Barley	68·38	67·56
Rye	62·64	61·55
Wheat	64·41	63·17

A combination of the Lindet method with the salicylic acid was tried with the object of securing a more thorough solution of the starch. Three grammes of the cereal were digested for fourteen hours at 45° C., with 30 c.c. of pepsin solution, the hydrochloric acid neutralized with sodium carbonate, and the substance heated

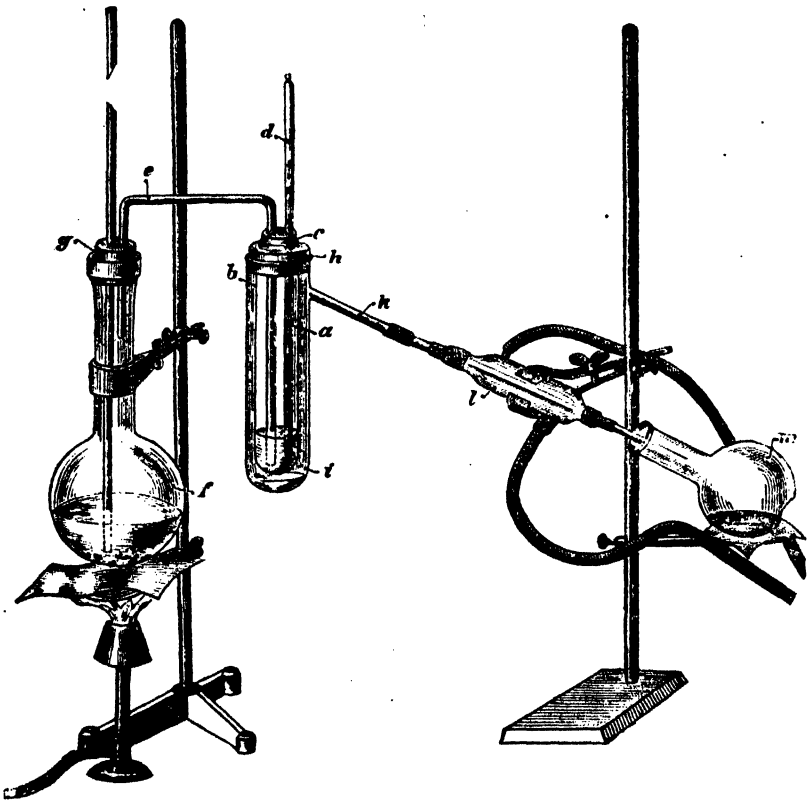
in the autoclave at 3½ atmospheres, after the addition of 0·5 gramme of salicylic acid. The percentages of starch obtained showed a close agreement with those given by the salicylic acid method alone. The mean results from the same cereals as used in the other experiments were:

Oats, 47·26; Rye, 62·35; Wheat, 64·48.

The combination of the Lindet method with the diastase method is said to have given most satisfactory results, but this part of the subject is still being investigated. In general, the use of pepsin is recommended as a safeguard to ensure the starch completely dissolving.

The diastase method without pressure is very satisfactory with the precautions referred to above. The materials should be ground to the finest possible powder, and extracted with ether to remove the fat. The treatment with diastase should always be repeated after boiling and cooling to about 50° C. (the temperature at which, according to Lintner, the enzyme is most active), and the residue should not show any starch granules when stained with iodine and examined under the microscope. The use of taka-diastase presents many advantages, as it can readily be obtained free from reducing sugar.

The small amount of matter unaccounted for in a complete analysis of cereals is regarded by the authors as probably belonging to the complex class of carbohydrates known as pentosan-ligno-celluloses, but they consider that the quantity is only very minute in cereals, though probably much larger in stalks and straw, and other substances containing a large excess of ligno-cellulose compounds.



C A. M.

Estimation of Urea. G. Meillère. (*Repert. Pharm.*, 1898, [3], x., 59; through *Chem. Zeit. Rep.*, 1898, 96.)—Sodium hypobromite solution being very unstable, the author prefers to employ the reagent in a nascent condition, preparing it in the nitrometer from a bromide and strong sodium hypochlorite solution, which evolves 30 volumes of active chlorine. 10 c.c. of the urine are diluted with 40 c.c. of water and mixed with 5 c.c. of sodium hypochlorite solution, 5 c.c. of 10 per cent. caustic soda, and 1 c.c. of 20 per cent. potassium bromide. Owing to the dilution of the liquids, warming is scarcely necessary, and a reading can be made in five minutes.

F. H. L.

A New Process for Determining Molecular Weights by the Boiling-Point Method. W. Landsberger. (*Berichte*, 1898, xxxi., 458-473.)—The apparatus employed in this process consists of a test-tube, *a*, in the side of which near the top is a perforation, *b*. The tube is closed by means of a cork, *c*, through which passes a thermometer, *d*, and a conducting-tube, *e*, bent twice at right angles, and is fitted into a larger tube, *i*, connected by means of a side tubulure, *k*, with a condenser, *l*. One end of the conducting-tube passes to the bottom of the inner test-tube, whilst the other is connected with a flask, *f*, in which the pure solvent is heated over a small flame or on a water-bath. The vapour enters the inner tube in which is placed some of the solvent, and in from 2 to 6 minutes a constant temperature is reached, and the boiling-point determined. The inner tube is then emptied, a weighed

quantity of the substance—of which the molecular weight is to be determined—introduced together with some of the solvent, and the vapour again passed in from the flask. The temperature is observed every 8 seconds until 3 consecutive readings in agreement have been obtained. The apparatus is then disconnected, the inner tube, *a*, rapidly withdrawn, the opening *b* and the open end of the tube, *e*, closed with small rubber corks, the tube wiped externally and weighed. It is then washed out with alcohol and ether, dried, and again weighed, the difference between the two weighings giving the weight of solvent and the substance in the tube. The weight of the substance being known, that of the solvent is obtained by subtraction, and the molecular weight calculated by means of the usual formula.

The author gives a table of the results obtained with this apparatus, and these show a close agreement with the figures of other observers. The thermometer employed was graduated in $\frac{1}{20}$ths of a degree. It is stated that a determination can be made within 25 minutes. C. A. M.

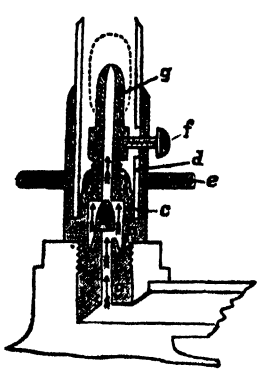
INORGANIC ANALYSIS.

Separation of Lead from Copper and Zinc; the Determination of Lead in Presence of Tin, and of Zinc in Bronze, etc. W. E. Garrigues. (*Proc. Eng. Soc., Western Pennsylvania*, 1898, xiv., 80.)—Lead chromate is quite unaffected by ammonia, whereas copper chromate is known to be readily soluble. If, therefore, to a nitric acid solution containing the three metals an excess of potassium bichromate is added,

followed by a decided excess of ammonia, and the liquid heated till the precipitate settles, the lead chromate may be filtered out on a single disc of paper in a Gooch crucible, washed with dilute ammonia, hot water, and alcohol, and finally dried in the water-oven and weighed. Antimony, iron, and probably bismuth interfere with the process.

If 0·5 gramme of a solder containing about 59 per cent. of lead is oxidized with nitric acid, 20 c.c. of strong sulphuric acid added, and the solution evaporated to the point of dense fuming, the meta-stannic acid dissolves completely. On diluting with not more than 80 c.c. of cold water, and stirring for a few minutes, the lead sulphate can be removed by filtration; then by making the filtrate alkaline with ammonia, and again acidifying with sulphuric acid till the liquid reddens methyl-orange, the tin can be recovered, ignited and weighed as stannic oxide. If care be taken not to use too much sulphuric acid, lead and tin may be removed in one operation; in fact, if the copper be thrown down with thiocyanate, the lead, copper, and tin can all be filtered off together, for washing with 3 per cent. sulphuric acid has no effect on either of the two latter precipitates. When small amounts of zinc have to be determined in bronze, the method is unequalled for exactness and speed. F. H. L.

Electrolytic Estimation of Manganese, and the Separation of Iron therefrom. **F. Kaeppel.** (*Zeits. anorg. Chem.*, 1898, xvii., 268.)—By the use of acetone it is possible quantitatively to deposit manganese from its solution as peroxide, to obtain it in the form of a sound coherent layer which can be safely washed even in amounts exceeding 1 gramme in weight, and to weigh it, after drying at 150° or 180° C., as MnO_2 with the certainty that it corresponds exactly to the composition represented by the formula. The original manganese solution, which should contain from 0·3 to 3·0 grammes of anhydrous sulphate, is made up to about 150 c.c., and mixed (proportionately) with 1·5 to 10 grammes of acetone. The liquid is raised to, and strictly maintained at, 50° to 55° C., and electrolysed with a current of 0·7 to 1·2 ampère at a tension of 4 to 4¼ volts for 2 to 5½ hours, the loss by evaporation being constantly made up. To prevent the formation of traces of permanganic acid at the cathode, this electrode should consist of two platinum plates suspended in the basin. The basin is the anode; and when large quantities of peroxide have to be recovered, it may with advantage be roughened with the sand-blast, as recommended by Classen in the case of lead. The deposit is washed without stopping the current (this operation being much simpler than when chrome alum, etc., has been employed), and finally dried for 1 to 2½ hours as aforesaid. Manganese peroxide is, of course, hygroscopic; but if the weighing be done quickly, or repeated after a second interval of drying, the error thus introduced is trivial. The examples quoted show results varying between 36·37 and 36·52 per cent. (mean 36·42 per cent.) in determining 36·42 per cent. of metallic manganese.

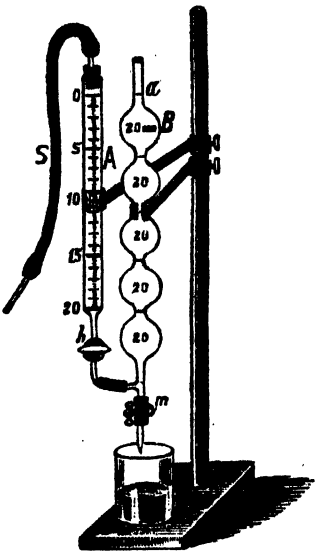


A rough separation of iron and manganese—the former being deposited as metal, and the latter (almost entirely) held in solution as permanganic acid—may be effected as follows; and though it leads constantly to a deficit of 0·3 to 1·0 per cent. in the iron recovered, as it requires no attention, but, proceeding at ordinary temperatures,

may be left going all night, the author thinks it may be found serviceable for some commercial purposes. Moreover, it is the more accurate the larger the proportion of iron in the sample tested. The liquid, which may contain between 0·35 and 1·0 gramme of $FeSO_4 + 7H_2O$ with 0·08 or 0·17 gramme of $MnSO_4$, is poured with constant stirring into a boiling solution of 6 grammes of sodium pyrophosphate; as soon as the whole is clear, 3 or 4 drops of phosphoric acid are added, and, if they produce a turbidity, a little more pyrophosphate. When the liquid is cold, it is electrolysed for 10 to 14 hours with a current of 0·7 to 1·8 ampère and 3·75 to 4·25 volts. The metallic iron adheres firmly to the platinum vessel, which, therefore, need not be given a matt surface; it is washed without stopping the current, rinsed several times in absolute alcohol, and dried at a moderate temperature.

If the electrolysis is conducted at a temperature of 35° to 40° C., the amount of pyrophosphate may be increased to 12 grammes, while the total bulk of the liquid is about 250 c.c. Under these conditions, with a current of 1·8 to 2·5 ampères, the operation is complete in 8 or 9 hours, the quantity of manganese precipitated is very greatly diminished (only a few flakes of oxide are to be seen), and the above-mentioned error in the weight of the iron is practically eliminated. Working on a mixture of about 1 gramme of crystallized ferrous ammonium sulphate with 0·2 to 0·7 gramme of the corresponding manganese salt, the percentage of iron found in the former varied from 14·02 to 14·19 (mean 14·105) per cent. instead of the theoretical 14·28 per cent. Unfortunately, the residual manganese cannot be recovered by electrolytic agency. F. H. L.

APPARATUS.



Bunsen Burner with Screw Cock. R. Meyer. (*Chem. Zeit.*, xxii., 226.)—The part *a* in the centre of the foot of the burner is drilled out as shown by the arrows, and carries the cone *b*, which is firmly screwed to it. The burner-tube *d* is screwed to the part *a* at *c*. Over this is passed a tube provided with a disc *e*, and through this tube the screw *f* is passed, and made fast to the burner-nozzle *g*. The lower end of the burner-nozzle screws into the part *a*, so that it can be made to approach or recede from the cone according as it is screwed up or down.

The supply of gas is regulated by turning the disc *e*. When it is turned to the right, the lower end of the nozzle-tube gradually shuts down on to the cone *b*, stopping the supply, the reverse taking place when it is turned to the left. H. H. B. S.

Some Improved Measuring Apparatus. O. Bleier. (*Chem. Zeit.*, 1898, xxii., 298 and 376.)—The apparatus which the author has previously described (ANALYST, xxiii., 55, and 111) is only suitable for the measurement of a pre-determined volume of liquid, and does not lend itself to the process of titration; the following modification,

however, overcomes this disadvantage. A burette (A), graduated in the usual manner, and holding altogether x c.c., is joined base to base with a 5-bulbed tube (B), such as already figured, except that each graduated portion is of the same size, and also holds x c.c. If desired, a second tube (C) of similar construction may be added, in which every division should contain $5x$ c.c. Each vessel preferably carries its own stopcock, while the exit tubes are united into one common orifice closed with a clip. By suitable manipulation of the stopcocks, the bulk of the liquid (corresponding to a certain number of the graduated spaces) can be run out of B and (or) C; and the residue, which requires measuring exactly, out of the burette. Or, if only the latter is provided with a cock, the whole of the liquid can be drawn from B while the cock at the bottom of A is shut, and then by opening the cock, inserting a cork and rubber tube in the top of A and blowing in or withdrawing air, the liquid in B can be brought exactly to the level of one of the marks, and the total volume calculated from the space emptied both in A and B. F. H. L.

A Safety Pipette with Caoutchouc Tube Attachment. **K. Zulkowski.** (*Chem. Zeit.*, xxii., 226.)—The usual form of pipette, whether graduated or constructed to deliver definite quantities, has many disadvantages. When the liquid is sucked up by the mouth, the eye is in an unfavourable position to observe the mark on the instrument and the level of the liquid, and consequently its use is not always altogether free from danger. In the case of large pipettes, the suction has often to be carried out intermittently, and the pipette cannot then be closed with the finger so quickly as could be wished. The adjustment is also often difficult, and there is a danger of the liquid becoming contaminated with the moisture from the mouth. The pipette shown in the accompanying sketch, which sufficiently explains itself, is designed to overcome these drawbacks. H. H. B. S.

REVIEWS.

THE ANALYSIS OF FOOD AND DRUGS.—PART I.: MILK AND MILK PRODUCTS. By T. H. PEARMAIN AND C. G. MOOR. (London: Baillière, Tindall and Cox, 1897.)

Considering that samples of milk and butter form the majority of all the samples taken under the Sale of Food and Drugs Act, and further that samples of milk and milk products are examined in large numbers for various purposes, a treatise on the analysis of dairy products must be regarded as a very desirable manual, the more so as the matter is by no means so simple and easy as on first sight it may appear to many an analyst. Proprietors of the back volumes of the ANALYST have the opportunity of instructing themselves very intimately on the subject, by studying the numerous articles on the composition and examination of dairy products contained in that journal; but the very fact that these are very numerous, and that they are scattered over the whole series of the twenty-two volumes of that journal, makes their perusal a difficult and time-taking task. Under these circumstances, one might say that the book under review meets a decided want. In their preface, the authors state that "in order to keep the book within manageable limits, they are compelled to deal briefly with, or sometimes merely to refer to researches, which would be rightly included in a larger work." Keeping this in mind, it is somewhat surprising to find so many pages devoted to remarks on practical dairying which might readily have been omitted, since many of them are inaccurate; indeed, we find in the book generally a deficiency in correctness of statement and exactitude of expression. Some of the obsolete methods of analysis might well have been omitted, and other processes described in greater detail; while the list of methods actually in use at the present time is not complete. The question of standards and limits is treated at length, without, however, advancing its solution. The chapter on the bacteriology of milk is too short to be exhaustive, and too long for merely touching upon this matter; it contains an account of some of the work lately done in this field of research. The best parts of the book are those treating of the detection of preservatives, and that on condensed milk. If the book, on reaching a second edition, which we hope it will do, is judiciously revised and corrected, it will become a valuable companion, not only to the analyst, but also to the better-educated dairyman. P. V.

APPLIED BACTERIOLOGY. By T. H. PEARMAIN AND C. G. MOOR. Second Edition. (London: Baillière, Tindall and Cox.) Price 12s. 6d.

This work, which we had the opportunity of favourably reviewing some eighteen months since (ANALYST, vol. xxii., 28), now appears in a second edition, and the fact that this is required in a little over twelve months from the publication of the original edition would appear to indicate that the book has fulfilled its mission. The new work is considerably enlarged, there being 457 pages of reading matter against 354 in the old; the arrangement of the several articles has been improved, and the whole work thoroughly revised and brought up to date. References to foreign publications are inserted for the first time. A new chapter on the bacteriology of sewage has been added, and also a new plate illustrating Mr. Stoddart's "Halo" cultures of the typhoid bacterium and its congeners. These additions and improvements cannot fail to render this useful book still more serviceable to all those who are concerned either in the study or in the practical application of bacteriology. W. J. S.

THE ANALYST.

SEPTEMBER, 1898.

OBITUARY.

THE LATE JOHN A. R. NEWLANDS.

It is with very deep regret that we have to record the death, on July 29, at Clapton, of one of our most respected vice-presidents, Mr. J. A. R. Newlands, who was in the sixty-first year of his age.

Mr. Newlands' memory will always be associated with the discovery of the "Periodic Law," which was afterwards worked out more fully and boldly by Mendeléef, Lothar Meyer, and De Chancourtois. Mr. Newlands' first communication on that subject was made to the Chemical Society in 1863 in the form of a note, and in 1866 he presented to that Society a paper entitled "The Law of Octaves, and the causes of the Numerical Relations amongst the Atomic Weights," in which his ideas were further elaborated. His views were received at that time with so much incredulity and even derision by the Chemical Society that they never found a place in its Journal, the subject being deemed of a too theoretical nature to merit publication. Nearly twenty-five years later, however, in 1887, Newlands' work met with authoritative, though tardy, recognition, for in that year the Royal Society awarded him the Davy Medal "for his discovery of the Periodic Law." In the region of applied chemistry he had for many years past devoted his energies mainly, in connection with his well-known brother, Mr. B. E. R. Newlands, to questions connected with the sugar industry.

Mr. Newlands, whose ancestors on the father's side were Scotch, and on the mother's Italian, was of a genial and enthusiastic nature; he was an earnest supporter of reforms in his own country, and even went so far as to serve as an English volunteer under Garibaldi in the war for the liberation of Italy.

We feel that we have lost in Mr. Newlands a remarkable and original man, and one whose affable and kindly disposition had endeared him to the hearts of all who knew him.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

ON CHICORY, AND VARIATIONS IN ITS COMPOSITION.

By Bernard Dyer, D.Sc.

(*Read at the Meeting, June* 1, 1898.)

Discrepancies between analysts in estimating the proportion of chicory in mixtures of chicory and coffee appear to be unfortunately frequent, and these may be attributed to varying assumptions as to the composition of the chicory present. As there is no satisfactory mode of separating coffee and chicory, the analyst is driven to base his calculations mainly upon the proportion of soluble matter in the sample, and on the assumed average proportions of soluble matter in coffee and chicory. Most analysts experimentally deduce their estimate of soluble matter, and hence the proportions of coffee and chicory, from the density of 10 per cent. infusion of the mixture, and a great many data are on record of the densities of such infusions of coffee and of chicory, but most of them are old. Some analysts—E. W. T. Jones, for example—prefer to evaporate a measured portion of the watery extract and actually weigh the soluble residue. Alfred Smetham in 1883 (Analyst, vii., 73) suggested thoroughly boiling out the sample with water, washing, drying, and weighing the insoluble residue on a counterpoised filter. It presumably makes but little difference which method is used, provided that the same mode of working is adopted for comparative purposes; but, as since the publication of Mr. Smetham's paper, I have myself always determined the insoluble matter directly, and the soluble matter by difference, it is in this form that I now propose to record some results of a recent investigation into the composition of the chicory at present in the market.

Mr. Bannister, in his evidence before the late Select Committee on Food Products Adulteration, in reply to a question from Sir Charles Cameron, endorsed an experience, attributed to Mr. Hehner, to the effect that the soluble matter in chicory appeared to have increased during the last ten or fifteen years, a fact which Mr. Bannister attributed to "difference of growth." My own experience confirms that of Mr. Hehner and Mr. Bannister, but I think there is no reason to suppose that the difference is due to methods of growth. It is more easily and probably accounted for by a custom of less highly roasting.

In 1883 I examined six samples of chicory obtained from various sources, with a view to their being representative of the chicory then in the market, and found that, calculated on the samples dried at 212° F., the matter insoluble in water, after exhaustively boiling and washing, weighed on the average 33 per cent., the variations being from a little over 30 to a little over 36. In 1895 I had occasion to examine a sample of chicory stated to be representative of that which was in use by a very large firm of wholesale grocers, and found only 22 per cent. of insoluble matter in the dried sample.

During the present year I took steps to obtain from several thoroughly representative wholesale houses samples of the chicory in current use, in all cases requesting to be supplied with samples representing any different grades of roasting or colour

that might be in current use. It may be stated that the percentage of moisture varied in extreme cases from 1 per cent. to 4 per cent., but the following results are all calculated on the dry substance. They show the total matter insoluble in water (inclusive of mineral matters), the ether extract, the nitrogen, the total ash, the ash soluble in water, and the sand.

	Total Matter Insoluble in Water.	Ether Extract.	Nitrogen.	Total Ash.	Ash Soluble in Water.	Sand.
	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.
Chicory "nibs," described as "medium roast" ...	22·40.	2·57	1·53	4 63	2·50	0·70
Chicory "nibs," described as "dark roast" ...	50·30	2·43	1·67	4·70	2 99	0·30
Ground chicory	22·27	2·17	1·33	5·53	2·43	1·43
,, ,, ...	21·50	1·90	1·34	5·23	2·07	1·43
,, ,, ...	35·50	3·43	1·50	5·13	2·57	0·77
,, ,, ...	37·80	3·87	1·52	8·23	1·60	3·97
,, ,, ...	22·77	3·17	1·25	5·13	3·30	1·60
,, ,, ...	22·50	3·67	1·23	5·73	3·23	1·63
,, ,, ...	23·50	2·60	1·29	5·63	2·97	1·47
,, ,, ...	22·50	2·60	1·29	5·33	3·20	1·47
,, ,, ...	22·63	2·57	1·29	5·70	2·60	1·47

It will be seen that in eight out of the eleven samples the matter insoluble in water ranged from 21·50 to 23·50 per cent. One sample contained 35·50 per cent., one 37·80, and one 50·30 per cent. of insoluble matter.

I have myself made no experiments to ascertain what percentage of insoluble matter is indirectly indicated by the figures usually assumed to represent the specific gravity of a 10 per cent. infusion of chicory, but I believe they may be taken as roughly corresponding to about 70 per cent. of soluble matter and 30 per cent. of insoluble matter, corresponding to the 70 per cent. of soluble matter assumed by E. W. T. Jones as representing chicory in his direct method of determination.

There is no doubt that, if the samples I have recently obtained fairly represent the chicory at present in the market—and I have every reason to think they do—any estimates deduced from density determinations with the aid of the older data would result in too high an estimate of the proportion of chicory, since they assume a much less proportion of soluble matter than that which is present in the greater part of the chicory at present in use. It is quite true, on the other hand, that with some kinds of chicory at present in use, reliance on the old figures might cause an error on the side of considerably underestimating the proportion of chicory; but an underestimate of the inferior article is, from the public analyst's point of view, obviously a matter of far less moment than an overestimate, which would reflect unjustly upon a seller of the article. It is indeed remarkable that, after attention had been drawn to the matter, the old figures should have still remained in use.

The following experiments were made with the sample marked "chicory nibs, medium roast," which gave originally 22·40 per cent. of insoluble matter. A portion

of the sample, after grinding and drying, was placed in a platinum capsule over a very low argand flame, and gently heated with thorough stirring until it had lost about 5 per cent. of its weight. A similar portion was similarly treated until it had lost about 10 per cent. of its weight. Calculating on the original weight taken, the proportion of insoluble matter in the first experiment rose from its original figure of 22·40 per cent. to 28·50 per cent., and during the second experiment it rose to 41·50 per cent. Seeing that there was a loss in the two experiments of 5 and 10 per cent. respectively, the percentage of insoluble matter in the actual roasted chicories would be 30 per cent. as the result of the first experiment, and 46 per cent. as the result of the second experiment. In neither case was there any appearance which could be described as that of burning. It seems clear, therefore, that the percentage of insoluble matter is mainly a function of the mode and duration of roasting.

It may be of moment to mention here that, on exhaustive boiling, Smetham, in 1882, found a number of coffee samples to contain about 75 per cent. of matter insoluble in water. Three samples of coffee of known purity which I examined in 1883 by this method gave from 72 to 73·3 per cent., averaging 72·9. In 1895 I made determinations in a batch of 16 samples of pure coffee, which showed a range of from 69·4 to 74·3 per cent., averaging 72 per cent. In 1897, 27 pure samples ranged from 71·8 to 75·9 per cent., averaging 73·7 per cent. I have found as little as somewhat over 68 per cent. of insoluble matter (on the dry sample) in a ground coffee in which no chicory was discernible, and which on all other grounds appeared to be genuine; but it is quite possible that in this, as in some other cases somewhat approximating to it, sugar may have been used in roasting the coffee, though no evidence was obtainable that such was the case.

Discussion.

Mr. Cassal said that quite five years previously he had found as much as 79 per cent. of soluble matter in chicory, and had in consequence been in the habit of depending upon the number 79, which almost exactly corresponded with the minimum figure now given by Dr. Dyer for insoluble matter, viz., 21·5 per cent. With regard to the samples yielding 50·3 and 37·8 per cent. of insoluble matter, it was evident that such cases were altogether abnormal, and that what could properly be regarded as "chicory" was not being dealt with. In a substance like chicory, continued roasting necessarily increased the proportion of insoluble matter.

Mr. Chattaway inquired whether the tinctorial power increased as the roasting was carried to a higher degree. A highly caramelized sample might be expected to yield a darker solution than one that has been less highly roasted.

Mr. Chapman observed that the relative proportions of soluble and insoluble matters would depend to some extent, not only upon the actual temperature, but also upon the conditions under which the roasting process was carried on. In roasting a substance like chicory, containing all kinds of caramelizable bodies, soluble compounds would be formed up to a certain point, after which such soluble compounds would to some extent be decomposed, with the result that the soluble matter, after reaching a maximum, would diminish again. In the manufacture of caramel from sugar, if the heating were effected too quickly, or the caramelized sugar poured into water at

too early a stage in the process, the maximum coloring power and soluble extract would not be obtained. It was, he thought, to be expected that considerable variations from what might be called the normal extract should from time to time be observed.

Mr. CASSAL added that he thought the figure usually taken for soluble matter in pure coffee, viz., 24 per cent., was sometimes too easily accepted. He had himself found as much as 29 per cent. of soluble matter in genuine coffee.

Dr. DYER said that he had once found 68 per cent. of soluble matter in a sample of coffee that was undoubtedly free from chicory. The sample, however, might have been roasted with sugar, and this was difficult to detect.

Dr. VOELCKER asked how much oil chicory usually contained.

Dr. DYER said that the oil was from 2 to 3½ per cent., but it did not seem to have any relation to the other constituents. In the sample containing 50 per cent. of insoluble matter the oil was 2½ per cent.; in the two lowest samples it was 2½ and 3½ per cent. respectively. The highly roasted samples were somewhat darker than the others, but in the case of a mixture the colour of the coffee itself would also be liable to variation.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Detection of Annatto and other Coloring Agents in Milk. J. Froidevaux. (*Ann. Chim. Analyt.*, vol. iii. [4], pp. 110-114.)—Of the various coloring agents added to milk, annatto and *orange III. Poirier* impart a flesh tint, saffron a slightly orange yellow, carrot an orange-yellow, and turmeric a slightly greenish-yellow tinge to the liquid. The last-named may be detected by the change to brown-yellow ensuing on the addition of ammonia. Hydrochloric acid (5 per cent. by volume) deepens the shade due to vegetable coloring matters and produces a clear rose coloration in presence of *orange III.*

The detection of these colorants is facilitated by coagulating the casein with a little rennet at 25° to 30° C. during fifteen hours, the colour lakes thus formed being more pronounced in shade—except in the case of *orange III.*—than when in solution.

Saffron and turmeric will impart a yellow stain to white filter-paper immersed in the whey for four days, the former colorant being distinguishable by the yellow stain—turning to slightly orange-yellow in presence of very dilute (*e.g.*, 2 per cent.) sulphuric acid—which it gives to filter-paper on immersion for four days in the liquid left after treating the milk with an equal volume of Adam's reagent,* and removing the

* This reagent, which is employed by Adam in his process for estimating fat in milk, consists of:

Alcohol (specific gravity 0·96°)	833 c.c.
Ammonia (specific gravity 0·925)	30 c.c.

These are made up to a litre with distilled water, and then 1100 c.c. of ether washed with water added.

upper ethereal layer of dissolved fat. Under the same treatment annatto gives an orange-red, changing to blue under the influence of 1 drop of strong sulphuric acid, and a bright rose colour in presence of a 2 per cent. solution of acid. C. S.

Detection of Annatto in Milk. A. Leys. (*Ann. Chim. Analyt.*, vol. iii. [5], pp. 149-151. See preceding abstract.)—The presence of this substance in milk can be detected more rapidly than by the method proposed by Froidevaux, if, after treating the suspected liquid with Adam's reagent and removing the supernatant ethereal solution, the casein in the lower layer be precipitated by the gradual addition of 50 per cent. of a 10 per cent. solution of sodium sulphate, without agitation. This treatment leaves the coloring matter in solution, from which it may be extracted by agitation with colorless amyl alcohol, the emulsion thus formed being dissipated by slowly heating the mixture to 80° C. The reddish alcoholic solution is evaporated to dryness and redissolved in hot, slightly alcoholized ammoniacal water, a strip of bleached cotton-cloth being immersed in the liquid, which is then concentrated on the water-bath. The cotton absorbs the coloring matter, and, after being lightly washed, is immersed in a weak acid (*e.g.*, citric acid), which in the case of annatto immediately changes the colour to a clear rose. This reaction does not ensue in the case of saffron, turmeric, etc., or in uncolored milk, notwithstanding that the cotton is dyed. C. S.

New Reactions for the Detection of Aldehydes in Alcohols. C. Istrati. (*Bulletinul Societatii de Sciinte, Bucuresci*, vol. vii. [2], pp. 163-170.)—The method adopted by Barbot and Jandrier (ANALYST, xxi., 295) can be improved by taking *exactly* 2 c.c. of the impure alcohol, adding thereto 0·2 c.c. of a saturated alcoholic solution of the reagent, and, after mixing the two, running in *exactly* 1 c.c. of sulphuric acid from a pipette, the tube being held at an angle of 45°.

The coloration produced at the moment of contact is noted, as is also the change after a lapse of half an hour. After partial agitation, to increase the surface of contact, the coloration is again noted at the end of half an hour, and once again half an hour after complete agitation. The liquid is then mixed with 10 c.c. of water, and examined half an hour and twenty-four hours later, the latter observation being extremely useful, as any precipitate formed will have had sufficient time to settle down.

Greater uniformity of conditions is ensured by the use of the alcoholic solution of the reagent, but such solution, being unstable, must be freshly prepared. In the case of liquid reagents, such as guaiacol, 1 drop is used instead of 0·2 c.c.

The reactions given by ten other substances than those examined by Barbot and Jandrier are tabulated below, those printed in italics referring to dilutions of $\frac{1}{10,000}$, and those in thick type to dilutions of $\frac{1}{100,000}$. The remainder refer to $\frac{1}{1,000}$ strength :

Estimation of the Dry Extract in Wine. **A. Celleri** (*Bull. du Ministère de l'Agriculture*, through *Ann. Chim. Analyt.*, vol. iii. [6], pp. 204-206.)—The period of evaporation may be reduced from the three days required for the Magnier vacuum method (ANALYST, xxi., 66) to seven and a half hours by employing a temperature of 80° C., and a U-tube apparatus with limbs of unequal diameter, the narrow one being connected with a bulb-tube containing sulphuric acid, and the larger one half filled with a piece of fine sponge, and fitted with an effluent tube for the condensation of the evolved vapour. This apparatus is dried by heating for about an hour over the boiling water bath until the difference between two weighings, at intervals of half an hour, does not exceed 1 milligramme. Ten c.c. of wine are then introduced by means of a pipette and absorbed by the sponge, and the tube is heated on the water-bath at 80° C.—a current of air being passed continuously through the apparatus—until found to be perfectly dry below the cork and of constant weight (with a latitude of 1 milligramme at half-hour intervals). The increase in weight represents the amount of dry extract in the wine.

At 80° C. the loss of glycerol by evaporation does not exceed 0·05 per cent., but this temperature should not be exceeded. The results obtained by this method are fairly constant, and are only 0·5 gramme per litre inferior to those yielded by evaporation *in vacuo*. C. S.

Action of Charcoal Decolorizers on Wines. **H. Astruc.** (*Ann. Chim. Analyt.*, vol. iii. [6], pp. 183-191.)—As the result of experiments with ten kinds of charcoal decolorizers, comprising crude and purified bone blacks, lamp blacks, and vegetable charcoal, the author concludes that there is little difference between the crude and purified animal blacks so far as their organoleptic and colorimetric influence on wine is concerned, the purified kinds being, however, slightly preferable. Their decolorizing power is best preserved by storage in a moist condition after washing.

All the decolorizers absorbed a little alcohol (0·4 to 1·5 per cent. out of a total of 7·8); a small proportion of the total acidity; 0·5 to 2·65 per cent. of the glycerol (total, 4·5 per cent.), and 0·95 to 2·65 per cent. out of a total of 3·45 per cent. of tannin, besides extracting coloring matter. The crude bone blacks are distinguished from the purified blacks and vegetable charcoals by removing almost the whole of the tartrates and a larger proportion of glycerol, and especially by increasing the amount of mineral matter in solution to double its original weight, the increase being entirely in insoluble ash-constituents (chiefly lime and phosphoric acid), whereas the soluble portion is diminished.

The decolorizing power of the vegetable blacks is low, and necessitates the use of a twofold or triple quantity, the effect of which on the chemical constitution of the wine is greater than that of a suitable amount of animal black. The flavour of the wine is also more seriously affected than by the latter. C. S.

The Estimation of Oil in Emulsions. **Dr. Schneegans.** (*Journ. Pharm. d'Alsace-Lorraine*, 1897, p. 323; through *Rev. Chim. Analyt. Appl.*, vol. vi. [8], p. 130.)—Three hundred parts of the oily emulsion under examination are evaporated with

50 parts of white of egg and coarse sand, 50 parts of anhydrous sodium sulphate being added and the evaporation completed, with continued stirring to prevent caking. The residue is pulverized and extracted with ether, the fat being recovered by evaporating the solvent in a tared beaker. C. S.

Acid Glycero-phosphates. Adrian and Trillat. (*Journ. Pharm. Chim.*, 1898, vii., 527-532.—The acid salts of glycero-phosphoric acid can be prepared by decomposing a normal glycero-phosphate with sulphuric acid:

$$2PO\begin{array}{l}\diagup O \\ -O \\ \diagdown OC_3H_5(OH)_2\end{array}\!\!>Ba + H_2SO_4 = BaSO_4 + PO\begin{array}{l}\diagup O-Ba-O \\ -OH \\ \diagdown OC_3H_5(OH)_2\end{array}\begin{array}{r} \\ -OP, \\ (OH)_2C_3H_5O\diagup\end{array}$$

or by double decomposition between a soluble sulphate and an acid glycero-phosphate:

$$Ba\left[OPO\begin{array}{l}\diagup OH \\ \diagdown OC_3H_5(OH)_2\end{array}\right]_2 + MgSO_4 = BaSO_4 + Mg\left[OPO\begin{array}{l}\diagup OH \\ \diagdown OC_3H_5(OH)_2\end{array}\right]_2$$

They are employed in the preparation of organic glycero-phosphates, such as those of quinine, cocaine, etc.

The method of determination given by the author is to dissolve from 1 to 2 grammes in 50 c.c. of water previously boiled, and to titrate the filtered solution with normal potash, using phenolphthalein as indicator. The amount of acid salt is then calculated from an equation like the following for the barium salt:

$$Ba\left[OPO\begin{array}{l}\diagup OH \\ \diagdown OC_3H_5(OH)_2\end{array}\right]_2 + 2KOH = H_2O + PO\begin{array}{l}\diagup O \\ \;\; O \\ \diagdown OC_3H_5(OH)_2\end{array}\!\!>Ba + PO\begin{array}{l}\diagup OK \\ -OK \\ \diagdown OC_3H_5(OH)_2\end{array}$$

Cf. Analyst (this vol., 45). C. A. M.

Estimation of Iodoform. G. Meillère. (*Ann. Chim. Analyt.*, vol. iii. [5], pp. 153, 154.)—The difficulties encountered in the estimation of iodoform in presence of organic substances may be overcome by the following method: The iodoform is placed in a flask where it is treated with 25 c.c. of pure nitric acid (free from chlorine), followed by a slight excess of silver nitrate (1·75 grammes per 1 gramme of iodoform), this order being observed in order to prevent the explosion resulting from the contact of iodoform and the silver salt in the dry state. The flask being connected with a Liebig bulb-tube containing silver nitrate solution, the contents are slowly heated, without actually boiling, for ten minutes, after which the temperature is raised to effect the decomposition of the iodoform. When nitrous fumes cease to be evolved, the liquid, after dilution to 150 c.c., is heated until clear, the precipitate is collected on a tared filter and washed, being finally dried at 100° C. Should the nitrate solution in the bulb-tubes become turbid, it must be united to the contents of the flask.

In two determinations made with 1 gramme of iodoform an average of 1·7835 grammes of silver iodide was obtained, the theoretical yield being 1·789 grammes.

TOXICOLOGICAL ANALYSIS.

A Strychnine-like Alkaloid found in a Corpse. P. Mecke. (*Pharm. Zeit.*, 1898, xliii., 300; through *Chem. Zeit. Rep.*, 1898, 128.)—During the examination of a partially decomposed body the author met with an alkaloid which chemically might easily be mistaken for strychnine, but which physiologically did not injure frogs, had scarcely a bitter taste, and did not produce the least effect on animals when injected subcutaneously. With picric acid it gave a yellow crystalline precipitate, becoming violet on treatment with sulphuric acid and bichromate. Bichromate alone produced a yellow crystalline precipitate, changing to blue with sulphuric acid. Bichromate and acid together yielded a blue, afterwards a reddish, colour. Ferricyanide gave a yellow precipitate, turned violet by acid. On the other hand, chlorine-water gave (as with strychnine) a milky liquid, but when after evaporation the residue was treated with ammonia it became a dirty green. It dissolved in sulphuric acid to a yellowish liquid, afterwards changing to cherry- and rose-red. Fröhde's reagent dissolved it, giving a dull violet colour, which finally became olive and then green. The substance is not the same as that discovered under similar conditions by Amthor in 1887.

F. H. L.

ORGANIC ANALYSIS.

The Examination of Semi-Woollen Textile Fabrics. S. Kapff. (*M. Text*, 1898, 193. Through *Zeit. angew. Chem.*, 1898, 452, 453).—In the author's opinion all the methods proposed for determining the proportion of cotton and wool in a mixture are inaccurate. He recommends the following process: Five grammes of the sample are extracted with ether for the determination of the fat. The residue is well stirred for thirty minutes in a mixture of 3 parts of hydrochloric acid with 100 parts of water, which is brought to the boiling-point before the introduction of the substance, and the flame subsequently withdrawn. It is then boiled with water for fifteen minutes, washed free from hydrochloric acid, dried for two hours at 100° C., and left exposed to the air for about twelve hours for the fibres to assume their original moisture. The loss in weight gives the amount of weighting material, coloring matter, etc. This treatment also removes certain natural constituents of the wool and cotton, whilst the fibres themselves are attacked, though but slightly.

The residual fibres are separated by heating them to the boiling-point with 250 c.c. of water containing 5 grammes of sodium hydroxide. The cotton which is left is collected on a filter, washed first with a litre of water, then with half a litre of water slightly acidified with hydrochloric acid, and finally with water until free from acid. It is then dried for two or three hours at 100° C., allowed to stand exposed to the air for about twelve hours, and weighed. The addition of 4·5 per cent. to the weight obtained gives the amount of cotton-fibre in the mixture, this correction being based on the results of experiments which showed that pure cotton-wool on treatment with soda as described above loses almost exactly that amount. C. A. M.

Estimation of Nicotine in Tobacco. C. C. Keller. (*Ber. Pharm. Ges.*, 1898, viii., 145; through *Chem. Zeit. Rep.*, 1898, 159.)—Six grammes of dried tobacco are repeatedly agitated during half an hour with 60 grammes of ether, 60 grammes of petroleum spirit, and 10 c.c. of 20 per cent. aqueous caustic potash. After standing three or four hours, 100 grammes of the ethereal liquid (equal to 5 grammes of tobacco) are filtered off, a powerful current of air is driven through it for one or one and a half minutes to remove the free ammonia, 10 c.c. of alcohol, 1 drop of a 1 per cent. solution of eosin B, and 10 c.c. of water are added, and the whole is well shaken. A slight excess of decinormal HCl is then run in, and the liquid is titrated with decinormal ammonia. One c.c. of $\frac{N}{10}$ HCl equals 0·0162 gramme of nicotine.

F. H. L.

Detection of Acetone in Urine. B. Studer. (*Schweitz. Wochenschr. Chem. Pharm.*, 1898, xxxvi., 149; through *Chem. Zeit. Rep.*, 1898, 127.)—The author's process is a combination of the Legal and the Lieben-Dragendorff methods. Fifty c.c. of urine and 5 c.c. of dilute sulphuric acid are distilled in a fractionating flask until about 3 c.c. have passed over. The distillate is mixed with 6 to 10 drops of a freshly-prepared 10 per cent. solution of sodium nitroprusside and 1 to 2 drops of caustic soda to make it alkaline. In the presence of acetone the liquid becomes purple-red; in its absence, yellow or orange. If a pale red is produced, suggesting a trace of acetone, 6 or 8 drops of glacial acetic acid are added, when an intense wine-red colour confirms the test; while, if the liquid turns yellow again, acetone does not exist in the urine.

F. H. L.

Estimation of Uric Acid, based on the Insolubility of Ammonium Urate. J. Triollet and J. Eury. (*Union Pharmaceut.*, May 5, 1898; through *Rev. Chim. Analyt. Appl.*, vol. vi. [10], p. 166.)—The authors recommend the employment of the method proposed by Otto Folin, 100 c.c. of urine being rendered slightly alkaline by agitating with 10 grammes of ammonium sulphate, and the precipitate, collected after two hours' standing, washed with 50 c.c. of a 10 per cent. solution of the same salt. It is then redissolved in (slightly alkaline) boiling water, the solution diluted to 100 c.c. after cooling, and treated with 15 c.c. of sulphuric acid, which causes the temperature to rise to 55° to 60° C. Titration is effected by the Hopkins method with $\frac{1}{20}$ normal potassium permanganate until a persistent rose coloration ensues, 1 milligramme being added to the result as correction for loss due to the solubility of the ammonium urate.

C. S.

Colorimetric Estimation of Aceto-acetic Acid in Diabetic Urine. F. Martz. (*Union Pharmaceut.*, May 15, 1898; through *Rev. Chim. Analyt. Appl.*, vol. vi. [10], pp. 165, 166.)—The reagent employed is ferric chloride, which gives a violet coloration with aceto-acetic acid in urine before, but not after, the latter has been boiled.

In cases where the coloration is due to this acid alone 5 c.c. of officinal ferric chloride are added to 100 c.c. of urine, and the filtered liquid is placed in a test-glass, where it is compared with 20 to 50 c.c. of a solution of 1 gramme of aceto-

acetic acid in 100 c.c. of water, plus 5 c.c. of the reagent, the test-liquid being made up with water until both liquids are of equal depth of colour.

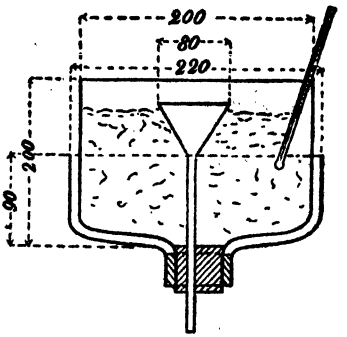
In presence of other substances giving the same reaction two determinations are necessary, one previous to and the other after boiling the urine, the coloration due to the acid in question being calculated from the difference between the two results.

C. S.

Detection of Glucose by means of Litmus. A. M. Julhiard. (*Ann. Chim. Analyt.*, vol. iii. [5], pp. 154, 155.)—Litmus being (like indigo carmine) decolorized by glucose in an alkaline solution, the author recommends the following as a ready test for the detection of that sugar in urine. A little sodium carbonate and a few drops of litmus tincture being added to the suspected urine, the liquid is heated to boiling, whereupon if containing sugar it will assume a dirty yellow colour. The reaction is more apparent after the precipitate has settled down, but it is not permanent, the blue coloration gradually reappearing on exposure to the air. Litmus-paper is also decolorized under the same conditions, and may therefore be conveniently employed instead of litmus solution. C. S.

The Estimation of Succinic Acid in the presence of Tartaric and Lactic Acids. F. Bordas, Joulin, and Raezkowski. (*Journ. Pharm. Chim.*, 1898, vii., 417, 418)—This is based on the difference in solubility of the silver salts of the three acids. On adding a concentrated solution of silver nitrate to a solution of their neutral soluble salts, the succinic acid is precipitated completely, the tartaric acid partially, while the lactic acid remains in solution.

In the determination, the solution containing the three acids is exactly neutralized with decinormal potash, an excess of a concentrated solution of silver nitrate added, and the precipitate filtered off and washed free from silver. Only the silver succinate is left on the filter, for the washing removes the silver tartrate completely.



The precipitate is washed into a flask, and two drops of a solution of potassium chromate added, which decompose the silver succinate with the formation of silver chromate. Decinormal sodium chloride is then added, until the precipitate becomes white and the liquid assumes a yellow tint, and finally the excess of sodium chloride is titrated with decinormal silver nitrate.

By subtracting the number of c.c. used in the last titration from the amount of sodium chloride taken, the volume of decinormal silver nitrate required to precipitate the succinic acid present is obtained. One c.c. of the silver nitrate corresponds to 0·0059 gramme of succinic acid. C. A. M.

Quantitative Estimation of Paraffin in Petroleum and Lignite-tar Distillates. D. Holde and L. Allen. (*Mittheil. Kgl. Techn. Versuchsanst.*, 1898, No. 2; through *Chem. Rev. Fett- u. Harz-Ind.*, vol. v. [6], pp. 112-115, [7], pp. 131-134.)—The present investigations were designed to ascertain the suitability of the alcohol-ether method for a wider series of oils than those previously tested therewith

(*Mittheilungen*, 1897, p. 211). The Aisinmann alcohol method was also critically examined.

The apparatus for cold filtration was altered to the form and dimensions shown in the annexed figure and acted well, enabling a constant temperature of −20° to −21° C. to be maintained with one charging long enough for the performance of a complete quantitative determination. The practice of ascertaining beforehand the minimum quantity of alcohol-ether necessary for dissolving the oil, and of effecting the solution of the latter at room temperature, greatly facilitates the subsequent operations and the separation of the paraffin, 0·4 per cent. of which was by this means recovered from a paraffin-oil wherein it was otherwise quantitatively undeterminable.

In applying the method to oils rich in paraffin, from 0·5 to 2 grammes of substance were dissolved in a minimum quantity of sulphuric ether, the solution clarified by the addition of an equal volume of absolute alcohol, and after insertion in the cooling-apparatus and dilution (if necessary) until filterable by the aid of alcohol-ether (1 : 1), the paraffin was separated by filtration. The filtrates were then evaporated and treated as before, in order to recover any residual dissolved paraffin. In all cases the paraffin was dissolved in petroleum spirit (b. p. 50° C.) and carefully re-evaporated, any moisture present being removed by evaporation with a little absolute alcohol.

As regards the solubility of paraffin in absolute alcohol, this was found to be greater than assumed by Aisinmann, 100 parts of solvent taking up 0·10 to 0·19 part at 20° C., and 0·015 to 0·017 part at −15° C. In alcohol-ether the solubility is greater (0·03 to 0·06 per cent. at −19° C. to −20° C.), and in both cases it varies inversely with the melting-point. The presence of oil in the alcohol-ether mixture, however, reduces the solvent power of the latter for paraffin, so that this source of error is counteracted when the method is applied for the estimation of paraffin in mineral oil distillates, the loss by solution ranging from 0·2 per cent. in oils containing 1 to 5 per cent. of hard paraffin, to an average of 1 per cent. in oils richer (30 to 90 per cent.) in that substance. For soft paraffins the results require to be compared with those obtained by treating mixtures of known paraffin content.

The objection urged by Eisenlohr against methods employing a higher temperature than 100° C. for drying the paraffin—on the ground that soft paraffin suffers loss by evaporation under such conditions—was investigated, but found to be baseless so far as the alcohol-ether method is concerned, the abbreviated (quarter of an hour) exposure to 105° C. resulting in a loss so small as to be negligable in technical analyses. On the other hand, a sample of paraffin supplied by Eisenlohr was found to lose considerably by this treatment, and it is therefore proposed in such cases to dispense with the evaporation at 105° C., and merely heat on the water-bath until the odour of the solvent disappears, the drying being completed in the desiccator.

Interesting results were obtained by applying the alcohol-ether method to lignite-

tar distillates, the figures obtained showing a yield of paraffin (m. p. 26° to 53° C.) from 1 to 3 per cent. higher than actually furnished in the refinery; and in one case the accurate characterization of the practical value of the material was shown by the recovery of 5 per cent. of worthless paraffin (m. p. 26° to 27° C.) from a distillate from which none could be separated in the factory. These experiences controvert Eisenlohr's opinion that the method is unsuitable for lignite-tar distillates.

An investigation of Aisinmann's alcohol method showed that accurate results are only obtainable when the paraffin greatly predominates (*e.g.*, 80 per cent.) in the mixture, and even then the alcohol-ether is preferable on account of its greater ease in manipulation. C. S.

The Reactions in Hübl's Method of Iodine Absorption. J. J. A. Wijs. (*Zeit. angew. Chem.*, 1898, 291-297.)—Ephraim (ANALYST, 1895, xx., 176) attributed the additive power of Hübl's solution to the presence of iodine monochloride, and described a method of determining the halogen absorption of fats by means of a solution of that substance. The author finds that the formation of the iodine chloride takes place in accordance with the equation

$$(1)\quad HgCl_2 + 4I = HgI_2 + 2ICl,$$

and considers that the equivalence of these substances is proved by the fact that it is possible to prepare a solution giving the same results as that of Hübl, by dissolving mercuric iodide in an alcoholic solution of iodine chloride.

The iodine chloride thus formed reacts with the water of the alcohol yielding hypoiodous acid and hydrochloric acid

$$(2)\quad ICl + H_2O = HCl + HIO;$$

and this acid is continually being slowly decomposed into iodic acid and free iodine, which substances in the presence of hydrochloric acid in alcoholic solution again produce iodine monochloride, so that a complicated equivalence results.

On adding the potassium iodide and water to the solution before titration, the following reactions take place:

$$(3)\quad ICl + KI = KCl + 2I;$$
$$(4)\quad HCl + HIO + KI = KCl + H_2O + 2I;$$
$$(5)\quad 5HCl + HIO_3 + 5KI = 5KCl + 3H_2O + 6I.$$

Theoretically in a blank determination the whole of the iodine should be found on titration, and the solution should contain no free acid, but in practice this is never the case, for the older the solution the less the iodine titre and the greater the acidity, the deficiency in iodine being equivalent to the acid formed. The author explains the alteration which occurs in the solution on keeping by the fact that hypoiodous acid oxidizes the alcohol to aldehyde.

$$2HIO + C_2H_6O = 2I + H_2O + C_2H_4O;$$

and that this causes a disturbance in the equivalence of the solution. Ordinarily each molecule of hypoiodous acid gives on titration (4) two atoms of iodine, but when there is aldehyde formation only one atom is liberated and the titre is correspondingly smaller. On the other hand, for each molecule of hypoiodous acid reduced a molecule

of hydrochloric acid is set free, which is not neutralized as in equation (4), and which therefore leaves the liquid acid. This hydrochloric acid the author terms "excess acid."

The stability of Hübl's solution may therefore be increased by keeping the concentration of hypoiodous acid as low as possible, as in Welman's method, in which alcohol is entirely or for the most part replaced by ether, ethyl acetate or anhydrous acetic acid. Waller (ANALYST, xx., 280) obtained the best results by adding strong hydrochloric acid, which acts not by combining with the water present, but by favouring the formation of iodine chloride and preventing its decomposition as in equation (2)

Of the substances taking part in the actual addition, free iodine is so slowly absorbed that it need not be taken into account in explaining the reaction. Like Ephraim (*loc. cit.*) the author formerly regarded iodine chloride as the chief agent in the addition, but has now come to the conclusion that the hypoiodous acid must be regarded as the principal substance. He argues that if iodine chloride were the most important, Waller's solution, which contains more iodine chloride, would act more rapidly than Hübl's solution, whereas experiments have shown the contrary to be the case. On the other hand, by shaking an alcoholic solution of iodine with finely divided mercuric oxide and filtering, the filtrate, according to Koene (*Pogg. Ann.*, lxvi., 302), contains mercuric iodide and hypoiodous acid, and with this solution correct iodine values were very rapidly obtained. A number of determinations of the iodine value of earthnut-oil, by means of Hübl's solution, to which various substances had been added, showed that when these substances favoured the formation of hypoiodous acid (*e.g.* iodine, mercuric chloride, and water), the halogen absorption took place more rapidly, whilst the converse was the case with substances which tended to repress its formation, such as hydrochloric acid and mercuric iodide.

In determinations of the iodine value there is invariably an increase in the "excess acid." The author considers that besides the addition of halogen, there is a further reaction with hydrochloric acid which, in the case of oleic acid, may be expressed thus:

$$CO_2H \cdot C_{17}H_{33}I \cdot OH + HCl = CO_2H \cdot C_{17}H_{33}ICl + H_2O.$$

But this only occurs without further change in strongly acid solutions like that of Waller. With solutions containing less acid there is a considerable increase in the "excess acid," which is to be accounted for by a splitting off of hydrochloric acid.

$$CO_2H \cdot C_{17}H_{33}ICl = CO_2H \cdot C_{17}H_{32}I + HCl.$$

The conclusions which the author has formed on this point are:

1. The separated acid is, *ceteris paribus*, proportional to the amount of absorption.

2. Under the same conditions different fats all yield about the same quantity of acid, proportional to the amount of fat taken. But with substances of a different constitution (allyl alcohol, cholesterol) different figures are obtained.

3. The greater the acidity of the solution, the smaller the quantity of acid separated.

4. The separation is most thorough in liquids which most readily dissolve hydrochloric acid. Thus it is greater in alcohol containing water than in chloroform, and in methyl alcohol than in ethyl alcohol.

In conclusion, the author summarizes the principal reactions which occur in the Hübl process in the following equations:

1. In the preparation:

$$HgCl_2 + 4I = HgI_2 + 2ICl$$
$$ICl + H_2O = HCl + HIO.$$

2. On keeping the solution:

$$2HIO + C_2H_6O = 2I + H_2O + C_2H_4O.$$

3. In the absorption (oleic acid):

$$CO_2H{\cdot}C_{17}H_{33} + HIO = CO_2H{\cdot}C_{17}H_{33}I{\cdot}OH.$$
$$CO_2H{\cdot}C_{17}H_{33}I{\cdot}OH + HCl = CO_2H{\cdot}C_{17}H_{33}ICl + H_2O.$$

And in a part of the fat:

$$CO_2H{\cdot}C_{17}H_{33}ICl = CO_2H{\cdot}C_{17}H_{32}I + HCl.$$

C. A. M.

A New Method of Determining the Iodine Absorption of Oils. J. J. A. Wijs. (*Berichte*, 1898, xxxi. [6], 750-752.)—In a former paper (ANALYST, preceding abstract) the author gave his reasons for concluding that in the Hübl process the substance chiefly concerned in the addition is hypoiodous acid, and he now suggests the more direct application of this acid as a means of improving the process. The fact, however, that it so readily decomposes ($5HIO = HIO_3 + 2H_2O + 4I$) prevents it being employed with any advantage at first hand. It was therefore found best to obtain the acid by the action of water on iodine chloride ($ICl + H_2O = HCl + HIO$), choosing a solvent which only contained so much of the former as would decompose nearly the whole of the latter, and which at the same time would not be oxidized by the hypoiodous acid. Good results were obtained with a solution of iodine chloride in 95 per cent. acetic acid. This was prepared by dissolving 13 grammes of iodine in a litre of the acetic acid, determining the "halogen content" of the solution and passing in a current of chlorine (free from hydrochloric acid) until the "halogen content" was doubled. With a little practice this point was readily hit by the change in colour. The solution thus prepared was more stable than that of Waller (ANALYST, xx., 280), and was employed precisely in the same way as Hübl's solution, with the exception that the length of time required for the absorption was very greatly reduced. In the case of oils with low iodine values, it was complete in three or four minutes, and with those with higher values not more than ten minutes was necessary, if too much oil had not been taken.

The following table gives the results obtained with this solution, compared with those of the ordinary Hübl process:

Oil.	Excess of Iodine. Per cent.	Time of Absorption.	I. Value.
Linseed	68	4 hours	180·91 (Hübl)
	57	5 min.	181·58
	57	7 ,,	182·25
	57	10 ,,	182·17
Liver-oil	61	4 hours	160·64 (Hübl)
	47	5 min.	164·79
	52	7 ,,	165·74
	65	8 ,,	166·51
	62	9 ,,	166·23
Maize ...	68	4 hours	124·87 (Hübl)
	65	3 min.	127·55
	64	6 ,,	128·56
	64	7 ,,	128·38
Poppy ...	69	4 hours	119·36 (Hübl)
	69	3 min.	119·66
	57	7 ,,	119·67
Sun-flower	70	4 hours	117·81 (Hübl)
	69	3 min.	118·92
	63	7 ,,	119·01
Sesame	69	4 hours	110·35 (Hübl)
	68	5 min.	111·87
	57	7 ,,	111·75
Cotton	68	4 hours	108·76 (Hübl)
	59	3 min.	110·07
	59	7 ,,	109·83
Rape	68	4 hours	102·96 (Hübl)
	65	3 min.	103·08
	61	7 ,,	103·33
Earth-nut	74	4 hours	87·26 (Hübl)
	70	2 min.	86·89
	70	3 ,,	87·13
	70	7 ,,	87·25
Olive	70	4 hours	83·27 (Hübl)
	70	3 min.	84·39
	70	7 ,,	84·45

In almost every case the values given by the new solution were higher than the ordinary Hübl values, but the author considered them the more correct by reason of the results obtained with purified allyl alcohol. This has a theoretical iodine value of 435. By Hübl's process Lewkowitsch obtained values varying from 349 to 376. Using an excess of 75 per cent. of iodine, the author found it to have an iodine value of 425 by Hübl's process, whilst with iodine chloride in acetic acid (the excess of iodine being the same) his results were: after five minutes 434·1 and after ten minutes 436·8. C. A. M.

Candle-Nut Oil. G. de Negri. (*Oesterr. Chem. Zeit.*,* 1898, i., 202.)—The following particulars respecting this substance were derived from the examination of two small samples extracted from seeds by the author himself: one with ether, the other with petroleum spirit. The yield was 62·25 per cent.; the product a bright, transparent, pale-yellow oil, which soon became rancid, and dried only a little more readily than tung-oil. It was soluble in ether, petroleum spirit, and chloroform; insoluble in cold absolute alcohol, with which it yielded a turbid mixture, but slightly soluble in hot alcohol. It did not dissolve in (? cold) glacial acetic acid; at the boiling-point it was soluble in equal volumes. It remained liquid at a temperature

* This is the same journal that was formerly known as the Zeitschrift für Nahrungsmittel-Untersuchung, Hygiene, und Warenkunde; and the corresponding reference is 1898, xii. [14], 202.

of – 18° C. It was readily saponified by alcoholic alkali, the soap being easily soluble in water. Some of the constants are given herewith:

	Extracted with Ether.	Extracted with Petroleum Spirit.
Specific gravity at 15°	0·926	0·920
Saponification number	187·36	184·0
Iodine number	139·34	136·29
Melting-point of fatty acids	20-21°	—
Solidification point of fatty acids...	13°	—
Iodine number of fatty acids	144·13	142·71
Refractometer number at 15° (Zeiss-Wollny) ...	—	76-75·5

With Brullé's test it gave no colour in the cold; on warming, a red which was permanent for twenty-four hours, while the oil became thick. Baudoin's test produced no colour. With Becchi's test the oil extracted by light petroleum yielded an intense brown; that recovered with ether only a faint brown. When exposed to the direct rays of the sun in sealed tubes for twenty-five days, both specimens of candle-nut oil, and also extracted tung-oil, remained perfectly liquid; whereas expressed tung-oil polymerized and formed some solid matter. Candle-nut oil recovered by carbon disulphide remained fluid when treated as above; tung-oil obtained by the same solvent solidified.

The material described by Laach (*Chem. Zeit.*, 1890, 871) was probably a mixture of fatty acids from different kinds of *aleurites*, for his figures are very unlike those observed by De Negri. F. H. L.

Improvements in Organic Combustion. F. Swarts. (*Chem. Zeit.*, 1898, xxii., 474.)—This process was originally devised for the ultimate analysis of compounds containing fluorine, but it is equally well adapted for all classes of organic bodies. In place of the ordinary glass tube, a seamless tube of copper is employed, about 1·5 metre long, 12 to 18 mm. in diameter inside, with walls 3 or 4 mm. thick. It is first cleaned by being ignited in a furnace while a current of air is passing through it; by which means also a coating of oxide is formed that materially assists in the combustion. In order to protect the corks at either end from being injured by the excessive heat due to the high conductivity of the metal, short jackets (about 12 to 15 cm. × 3 to 4 cm. in size) with corks and leading tubes are applied close to both extremities, and water is kept circulating through them. The combustion tube is charged much in the usual fashion; but instead of using copper oxide alone the author prefers a mixture of three parts of CuO with one of granulated PbO, the latter prepared by heating pure red lead to incipient fusion in a copper basin with constant stirring. The tube is laid in a Glaser furnace; the substance to be burnt in a boat. At the point where the boat stands, the bent iron bottom-plate of the furnace is removed, and its place is taken by a somewhat more deeply curved casting having a hole and leading tube at its lowest point. Immediately over the tube at the same spot is a short piece of copper pipe closed at each end, perforated underneath with many fine holes, and connected to a water-supply. By the aid of

a tap a stream of water (which afterwards runs away through the hole just mentioned) may be caused to play on the portion of the main combustion tube that surrounds the boat; and, by regulating or stopping the supply, the substance can be volatilized in the current of purified air at any desired speed. In this manner much time is saved, for the copper-lead oxide can be brought to a red heat while the weighings are in progress, and the organic body maintained cold when in position until the roll of oxidized copper gauze at the other end of the tube is also hot. When the combustion seems to be nearly finished, the rubber tubes for the delivery and exit of the water are disconnected, and the part of the copper tube round the boat is brought to a red heat for five or ten minutes in order to burn up the residual carbon. Some of the water from the oxidation of the material is condensed at the end of the tube by reason of the short condenser there fixed. This may be driven over into the absorbing vessel by stopping the current of water, emptying the jacket if necessary till the deposited moisture boils again; but the amount retained within the tube may be reduced to a minimum by so regulating the current that the extreme ends of the copper are kept slightly warm all through the operation.

Not only can the copper tube be raised to the working temperature almost instantaneously, but the speed of the combustion itself is under ready control. Compared with these advantages, the lack of transparency is not a serious obstacle, for the progress of the operation can be gathered by watching the potash bulbs. The coating of copper oxide in the tube prevents the deposition of very resistant carbon; and the tube itself lasts for about sixty analyses before being worn out.

F. H. L.

Kjeldahl's Method and its Modifications. A. Atterberg. (*Chem. Zeit.*, 1898, xxii., 505.)—Reviewing seven different modifications of the original Kjeldahl process in a recent work on chemistry, the author stated that Kellner's seemed to be the best and quickest. The matter has now been further investigated, using as a test-substance a bog-earth containing 15 per cent. of moisture and 7 per cent. of ash, and conducting the oxidation as fast as possible in a 250 c.c. flask. Gunning's method occupies ninety-five minutes, and much frothing occurs; if a drop of mercury is added, the time is roughly halved; if the potassium sulphate is not introduced till the material is dissolved (the proportion between the H_2SO_4 and the K_2SO_4 being kept as specified by Gunning), the process only takes about twenty-six minutes, and no foaming is noticed. Kellner's method requires forty-five minutes, which may be reduced to twenty-seven by the employment of potassium sulphate. The latter substance therefore is just as efficient as Kellner's phosphoric anhydride—both raise the boiling-point of the sulphuric acid; and orthophosphoric acid itself might be used instead of the anhydride were it not for the separation of mercury phosphate, which interferes with the boiling of the liquid. Experiments have been tried with metals or oxides other than mercury, in order, if possible, to avoid the necessity for adding sulphide when distilling off the ammonia. Only molybdic acid (*cf.* ANALYST, xxi., 267) has been found to work without frothing; but as the oxidation is made a trifle slower, the final solution is blue instead of colorless, and commercial specimens of the reagent often contain much nitrogen, it can hardly replace mercury.

The author quotes some figures obtained with sulphate of quinine which go to prove that the best oxidizing solution is composed of 20 c.c. of strong sulphuric acid, 15 to 18 grammes of potassium sulphate, and a little mercury. When frothing is expected, the sulphate should not be introduced till the nitrogenous body is dissolved, otherwise it may be added at the outset. Decolorization takes place (in a 250 c.c. flask) in about 30 minutes; but the whole should be boiled 15 minutes longer.

F. H. L.

Detection of Sulphur and of Nitrogen in Organic Bodies by means of Phloroglucinol and Vanillin. P. N. Raikow. (*Chem. Zeit.*, 1898, xxii., 377.)—The red colour which is produced in a dried alcoholic solution of phloroglucinol and vanillin by the action of the halogens has already been described (ANALYST, xxiii, 99). A similar reaction is determined by sulphur, phosphorus, and arsenic; and in the case of sulphur it is so general that the test is available for the examination of organic substances of whatever kind. It shows the presence of thiophen in benzene, and it distinguishes between the proportion of the impurity in German, Russian, and Pennsylvanian petroleum. Sulphuretted hydrogen does not yield the red colour; it is derived from sulphurous oxide, and the test is so delicate that if methyl thiocyanate is diluted with alcohol, and a drop equivalent to 0·001 milligramme of sulphur is burnt, the coloration is still visible.

As Becchi's test for cotton-oil depends on the sulphur it contains, experiments have been made (and are still unfinished) on various oils with the present reagent. Sesamé, castor, walnut, olive, arachis, white cod-liver, and huile de Veillette, give no colour. Cotton, colza, linseed, rape, and seal, yield a more or less intense red. The colour produced by linseed-oil is much fainter than that of colza or cotton-oil, and the degree of volatility of the compound which contains the sulphur varies largely in different oils, that in cotton-oil having such a high volatilizing point that the strength of the reaction is not diminished when the oil is treated with steam for twelve hours. All of these oils contain but little sulphur, and as many burn with a very smoky flame, the test is rather difficult to carry out. The sample is best burnt in a glass tube bent at a right angle close to the end; in the bend is placed some long fibre asbestos to act as a wick, and the size of the flame is regulated by altering the position of the tube. If the flame be kept quite small and held very near the lid of the porcelain crucible which bears the dried film of reagent, the colour soon appears; but if the soot is still troublesome the oil may be diluted with ether or alcohol.

All kinds of albumin, fibrin and casein give a fine red colour, as do also all varieties of paper, even filter-paper.

The behaviour of nitrogenous organic matter with the mixture of phloroglucinol and vanillin depends on whether the compounds evolve their nitrogen as acid, ammonia, or in the free state, when they are broken up. If a few drops of the reagent are mixed with one drop of nitric acid, and the whole set light to, an intense red colour is produced; under similar conditions ammonia gives a bright yellow. No colour at all is formed when any nitrogenous substance is held in a loop of platinum-wire in a powerful Bunsen flame under the porcelain lid, because the nitrogen is set

free. No colour is produced if nitro- or nitroso-compounds or nitriles are allowed to burn by themselves; but amines and similar bodies give a yellow. Aromatic compounds in which the nitrogen is part of the closed chain as a rule give no yellow, *e.g.*, quinoline, piperidine, etc., but antipyrin and isatin yield faint yellows. The test will show 1 per cent. of aniline in quinoline.

When nitrogenous bodies which give the yellow reaction also contain sulphur or a halogen, the red colour is produced as well, *e.g.*, thiourea, chloraniline, methyl violet, etc., also wool, hair, feathers, casein. But sometimes a faint red is to be found even in the absence of sulphur and chlorine, as part of the nitrogen has burnt to acid; in this case the sample should be decomposed in the Bunsen flame, when no red will be observed.

Raikow prefers to dissolve the phloroglucinol and vanillin in ether rather than in alcohol, as the solution is more permanent, and also to use it much weaker than recommended by Günzburg. F. H. L.

Remarks on the Estimation of Tannin, and on the Titration of Tannin and Gallic Acids. F. Jean. (*Ann. Chim. Analyt.*, vol. iii. [5], pp. 145-149.)—The author confirms the observation made by Raŭ (*Jour. Amer. Chem. Soc.*, vol. ix., No. 4), that up to 50 per cent. of gallic acid is fixed by hide powder and other gelatin-yielding tissues, and also demonstrates that, in order to more closely approximate laboratory results to those obtained in tannery practice, the Hammer method requires modification to render it suitable for the estimation of tannin and substances which can be fixed by the hide. With this object he proposed to replace the treatment with hide powder by forty-eight hours' maceration with finely-shredded rabbit-skin—the anatomical structure of which has not been destroyed—since he finds that by this means the fixation of gallic acid is reduced from 42 per cent. to 27 per cent.

Similarly, the Hammer method is unsuitable for determining the tannin and gallic acid in astringent bodies, such as sumach. In this case, albumin proves the best means of separating these two substances, a sumach that yielded 2·396 per cent. of gallic acid when treated with hide powder furnishing 13·4 per cent. of the acid by the albumin method. The loss of gallic acid observed when working with a mixture of known composition is reduced by this latter method to 2·2 per cent.

C. S.

Method of Preparing Pure Sugar. H. Pellet. (*Bull. Assoc. Chim. de Sucr. et Distill.*, vol. xv., p. 813; through *Rev. Chim. Analyt. Appl.*, vol. vi. [9], p. 143.)—Five hundred grammes of refined loaf-sugar are dissolved in 250 grammes of distilled water and filtered if necessary. To the clear solution 560 to 570 c.c. of absolute alcohol are added by degrees, the liquid being agitated to prevent crystallization, and afterwards covered up and set aside for several days to allow the excess of sugar to crystallize out. The supernatant liquid is then poured off, and the crystals—which are loosened from the walls of the vessel by immersing the latter in warm water—are collected in a tapped funnel, and washed with alcohol increasing in strength from 70 per cent. to 100 per cent. Finally, they are dried over sulphuric acid, and a

10-gramme sample is incinerated to test the freedom from ash. If found impure, the crystallization process is repeated. C. S.

INORGANIC ANALYSIS.

The Separation of Mercury and Bismuth. L. Vanino and F. Treubert. (*Ber.*, 1898, xxxi., 129, 130.)—This is based on the fact that on adding to a dilute hydrochloric acid solution of mercuric chloride and bismuth oxychloride a mixture of hypophosphorous acid and hydrogen peroxide (1 drop of the former to 1 c.c. of the latter), the mercury is separated quantitatively as calomel, while the bismuth remains in solution, and can be precipitated by the further addition of hypophosphorous acid. The details of the method are as follow:

The solution of the mixed salts is treated with the reagent as above, and, after standing for about an hour, the precipitated calomel is filtered off, rapidly washed free from bismuth, first with dilute hydrochloric acid, and subsequently with cold water, and dried at 105° C.

The filtrate is made slightly alkaline with sodium hydroxide, warmed over a naked flame, and hypophosphorous acid added until no more black precipitate is produced, and no turbidity occurs in the supernatant liquid on the addition of water. The precipitate is pressed into a compact mass with a glass rod to prevent oxidation during the drying, collected on a Gooch's filter, washed successively with water and alcohol, and dried at 105° C.

A table giving the results of the method applied to a test mixture shows that the figures obtained in this way are in close agreement with those required by theory.

C. A. M.

Qualitative Separation of the Metals of the Iron, Chromium, etc., Group, and of the Rare Earths. G. Posetto. (*Giorn. di Farm. di Trieste*, 1898, iii., 70; through *Chem. Zeit. Rep.*, 1898, 135.)—The original solution is treated with ammonia and ammonium sulphide, and separated into a filtrate (A) and a precipitate (B) containing the hydrates of Fe, Cr, Al, Ce, La, Th, Zr, Y, U, Be, Di, the sulphides of Mn, In, Ni, Co, and the phosphates, etc., of Ba, Sr, Ca, and Mg. This is warmed with 1 : 5 HCl, which dissolves everything except the Ni and Co. The solution (C) is mixed with nitric acid, boiled for a time, then cooled, and made just alkaline with strong KHO. Only the Be is left unprecipitated, and it is thrown down on diluting the liquid with three or four times its volume of water and then boiling. The precipitate (D) is boiled in KHO to remove Al and Zn, and the insoluble matter (E) is washed and digested in ammonium carbonate solution with occasional agitation for twelve hours. The filtrate (F) contains the carbonates of Ce, Th, Zr, La, U, Di, and Y; the residue (G) Mn, Fe, Cr, and Ba, Sr, Ca, Mg as phosphates, borates, etc. After the Mn, Fe, and Cr have been specially tested for in small quantities of (G), the main portion is boiled for ten minutes with sodium carbonate solution, which decomposes the bulk of the phosphates, etc., of the alkaline earths into carbonates, giving a solution (H) and a precipitate (L). The latter is dissolved in HCl, precipitated with ammonia and

sulphide, the insoluble portion is thrown aside, and the filtrate, mixed with the first solution (A), is examined for alkaline earths and alkalies as usual.

(F) is boiled till the carbonates are deposited and the liquid yields no residue on evaporation. The precipitate (N) is divided into different parts: (1) Is mixed with hydrogen peroxide—in presence of Ce the white powder changes to yellow—or it is boiled with excess of nitric acid and lead peroxide, when the liquid becomes yellow. (2) Is treated in a porcelain basin with a few crystals of iodine—La causes the mass to turn blue. (3) Is dissolved in water containing a trace of HCl and subdivided into three. Turmeric paper is dipped into (3*a*) and dried at 100° C.—a red colour like that produced by boric acid indicates Zr. (3*b*) Is tested with potassium ferrocyanide—U gives a red colour or precipitate. (3*c*) Is treated with sodium carbonate —Di forms a white precipitate insoluble in excess. A fourth portion of (N) is dissolved in weak HCl, neutralized with KHO, a few crystals of normal potassium sulphate added, and the whole boiled. Th, Zr, and Ce are thrown down as double sulphates (O). The filtrate is again boiled several times to ensure the removal of all insoluble matter; but Y remains in solution, and may finally be recovered on addition of ammonia. The precipitate (O) is boiled in HCl and water—the double sulphates of Th and Ce dissolve, that of Zr remains unattacked. The solution is treated with oxalic acid to throw down the earths, and the precipitate is boiled in strong ammonium oxalate till it dissolves. After cooling, the liquid is diluted with three times its volume of water, which deposits the oxalate of Ce. The Th is recovered from the filtrate by treatment with ammonia. F. H. L.

Precipitation of Platinum from its Solutions. A. Atterberg. (*Chem. Zeit.*, 1898, xxii., 538.)—Of the numerous substances which may be employed to throw down metallic platinum from its solutions, thiacetic acid, mercury, and magnesium are the most useful. The first yields a particularly voluminous precipitate, and it is therefore to be recommended when only traces of the metal have to be dealt with. When it is desired to estimate the sodium in the alcoholic filtrate from a potash determination mercury is the best reagent. The platinum solution is concentrated to a small volume on the water-bath in a deep porcelain basin, an excess of mercury is added, and the whole is well stirred till the reaction is complete. The by-product is mercuric (not mercurous) chloride, and can easily be removed by heat. The reduction only takes place in the warm; the platinum is deposited as a compact powder, but the operation must never be conducted in a platinum vessel, as the metal sticks firmly to the walls. If the platinum which is in solution has to be weighed, the best precipitant is magnesium ribbon. The liquid may be neutral, but it is better acidified with a little hydrochloric acid. The deposition proceeds slowly in the cold, more quickly on warming or on agitation; but a trace of metal remains in solution for some time, giving it a grayish colour, so that the liquid should not be filtered until it is water-white. The platinum is heated with HCl, washed very thoroughly, and gently ignited.

For working up alcoholic platinum residues magnesium ribbon is also most

convenient. In twenty-four hours all the metal is thrown down, and can be decanted off, purified with acid, and washed. F. H. L.

Separation of Nickel and Cobalt with Potassium Nitrite. Schlagdenhauffen and Fageot. (*Bull. commerc.*, 1898, xxvi., 225; through *Chem. Zeit. Rep.*, 1898, 170.)—When describing this process, the books usually require that the solution of the metals shall be treated with an equal volume of nitrite and an excess of acetic acid. The present authors find that this is not sufficiently explicit to ensure uniform results. The strongly concentrated liquid containing the metallic chlorides must be mixed with a cold-saturated solution of potassium nitrite, diluted with at least five times its volume of water, and 15 to 30 c.c. of acetic acid added for every 1 gramme of chloride present. The nickel remains in solution and the cobalt is completely precipitated, so that the method serves for their quantitative separation, or for the detection of traces of either one in the other. F. H. L.

The Colorimetric Estimation of Small Amounts of Chromium. W. F. Hillebrand. (*Jour. Amer. Chem. Soc.*, 1898, xx., 454-460.)—The chromium is brought into solution as monochromate, the liquid rendered alkaline with sodium carbonate, and compared with a standard solution of chromate, also made alkaline with sodium carbonate. Two standards are prepared, containing 0·25525 and 0·5105 gramme of potassium chromate per litre respectively, a little sodium carbonate being added to each. One c.c. of the first solution corresponds to one-tenth of a milligramme of chromium oxide.

In testing the applicability of the method to the determination of chromium in rocks and ores, varying amounts of the standard solution were evaporated in a crucible with 5 grammes of an iron ore containing phosphorus and vanadium, and the residue fused with 20 grammes of sodium carbonate and 3 grammes of sodium nitrate. The aqueous extract was nearly neutralized with nitric acid after the reduction of the manganese with alcohol, and was evaporated so as to approximately separate the silica and alumina. In order to recover any chromium carried down with these, the precipitate was ignited, the silica removed by treatment with sulphuric and hydrofluoric acids, the residue fused with sodium carbonate, the alumina separated as before, and the filtrate added to the first filtrate. Mercurous nitrate was then added, and the resulting precipitate, containing phosphate, chromate, vanadate, and carbonate of mercury, was slightly washed and ignited. The residue was fused with sodium carbonate, extracted with water, filtered, the solution made up to 50 or 100 c.c. and the colour compared with the standard, as in a Nessler determination of ammonia. A similar determination was made with a silicate rock.

	Chromic Oxide added. Milligrammes.	Chromic Oxide found. Milligrammes.
1. Five grammes iron ore ...	7·03	7·18; 7·20; 7·25; 7·21
2. ,, ,, ...	2·99	3·08; 3·13
3. Two grammes silicate ...	1·6	1·53; 1·57; 1·59

When the percentage of chromic oxide in an ore exceeds two-tenths per cent., and a vanadium determination is not required, the colour of the original extract of the carbonate fusion may be matched after reduction and removal of the manganese, but when much less than that quantity is present the precipitation with mercurous nitrate is necessary to obtain a sufficiently colored filtrate in a small bulk.

C. A. M.

The Volumetric Determination of Vanadium in the Presence of Small Amounts of Chromium. W. F. Hillebrand. (*Jour. Amer. Chem. Soc.*, 1898, xx., 461-465.)—When chromium and vanadium occur together, and the former has been estimated colorimetrically (see preceding abstract), the vanadium can in many cases be determined without separation from chromium by reduction with sulphurous acid and titration with permanganate in sulphuric acid solution. The one limitation to the method is that too much chromium must not be present, since it interferes with the end-reaction; but satisfactory determinations of as little as 1 or 2 milligrammes of vanadium pentoxide can be made in the presence of 30 milligrammes of chromic oxide. The method is not applicable in the presence of molybdenum, and arsenic, if present, must be removed by precipitation with sulphuretted hydrogen.

The rock or ore (free from arsenic) is fused with sodium carbonate and nitrate, the melt extracted with water, the manganese reduced, the silica and alumina removed, and the chromium determined colorimetrically, as described in the preceding abstract.

After the colorimetric determination, sulphuric acid is added, the chromium and vanadium reduced by means of sulphur dioxide, and the excess of the latter expelled by boiling the liquid in a rapid current of carbon dioxide. When cooled to about 70° or 80° C., the solution is titrated with a very dilute standard solution of potassium permanganate, of which 1 c.c. corresponds to about 0·001 gramme of vanadium pentoxide as calculated from its equivalent in iron.

The subjoined table gives the results of test analyses of an iron ore and silicate rock to which known amounts of chromium and vanadium had been added:

	Chromic Oxide added. Milligrammes	Vanadium Pentoxide added. Milligrammes.	Vanadium Pentoxide found. Milligrammes.
Iron ore, 5 grammes ...	7	6·76	6·81; 6·48; 6·43; 6·37
,, ,, ...	8	3	3·08; 3·13; 3·03
Silicate, 2 grammes ...	1·6	1·87	1·86; 1·97; 2·07; 1·86

C. A. M.

The Iodometric Estimation of Tellurium. J. F. Norris and H. Fay. (*Amer. Chem. Jour.*, 1898, xx., 278-283.)—Attempts were made to employ the volumetric method found satisfactory in the case of selenium (ANALYST, xxii., p. 82) in the estimation of tellurium. One molecule of tellurous acid reacts with four of sodium thiosulphate in the presence of dilute acid, but the end-point is not sharp, since the addition of the thiosulphate produces a yellow solution, and the reduced tellurium compound is slowly oxidized by iodine.

A more successful method was found in the oxidation of tellurous acid to

telluric acid by means of potassium permanganate, and determination of the excess of the latter by adding potassium iodide and sulphuric acid, and titrating the liberated iodine with thiosulphate.

The reactions involved in the process are:

$$(1)\ 2KMnO_4 + 3TeO_2 = K_2O + 2MnO_2 + 3TeO_3,$$

in which the manganese is not precipitated, but remains in solution probably as a manganite or in combination with the telluric acid.

On adding to such a solution potassium iodide and sulphuric acid, the following change occurs:

$$(2)\ 2MnO_2 + 4KI + 4H_2SO_4 = 2MnSO_4 + 2K_2SO_4 + 4H_2O + 4I.$$

Any excess of permanganate reacts thus:

$$(3)\ 2KMnO_4 + 10KI + 8H_2SO_4 = 2MnSO_4 + 6K_2SO_4 + 8H_2O + 10I.$$

Combining equations (1) and (2), the oxidation of tellurium dioxide may be thus expressed:

$$(4)\ 2KMnO_4 + 3TeO_2 + 4KI + 5H_2SO_4 = 3TeO_3 + 3K_2SO_4 + 2MnSO_4 + 5H_2O + 4I.$$

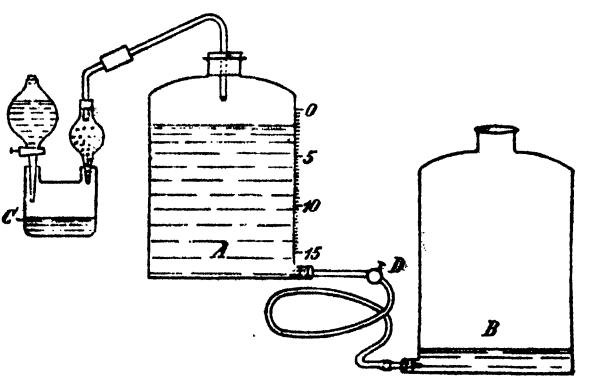
The precautions to be observed are that the oxidation must take place in the presence of a large excess of alkali, and that the solution must be dilute and cold in order to prevent the reduction of the telluric acid by the hydriodic acid.

A sample of pure tellurium dioxide analyzed in this way gave eight results varying from 79·80 to 80·15 per cent. of tellurium, as against 79·94 per cent., the theoretical amount. The accuracy of the method in the presence of halogen acids was proved by the analysis of the double bromide of tellurium and potassium with which four consecutive results (18·58 to 18·64 per cent.) were obtained, the theoretical percentage of tellurium being 18·61.

Experiments proved that this method is also applicable to the determination of selenium, but it offers no advantages over the simpler method proposed before.

C. A. M.

Estimation of Various Sulphides by Titration with Permanganate. J. **Hanus.** (*Zeits. anorg. Chem.*, 1898, xvii., 111.)—The sulphides of antimony, lead, and bismuth are oxidized by treatment with ferric sulphate, and the reduced ferrous salt can be titrated with permanganate in the usual way. Tin and cadmium behave similarly, as mentioned by Mohr; but the reaction with copper is not complete, and the sulphides of mercury and arsenic cannot be determined in this manner. About 0·2 or 0·3 gramme of precipitated antimony trisulphide is washed into a beaker and boiled for 15 minutes with excess of powdered ferric sulphate; after cooling, sufficient strong sulphuric acid (15 c.c.) is added to dissolve the precipitate, and when this is effected the clear liquid is made up to 200 c.c., filtered through a dry filter, and 100 c.c. taken for titration with the permanganate. Free sulphur does not affect the process; but the precipitate must be entirely dissolved in the sulphuric acid, and it must not be exposed to air, or some inert red oxysulphide may be produced. The reaction is as follows:

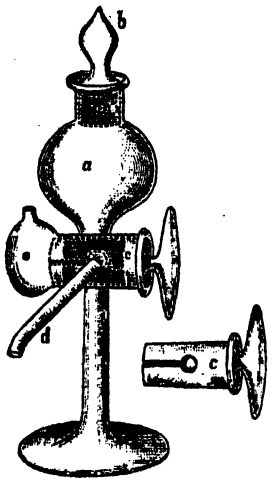


$$Sb_2S_3 + 5Fe_2(SO_4)_3 + 8H_2O = 2H_3SbO_4 + 10FeSO_4 + 5H_2SO_4 + S_3.$$

With lead the process works satisfactorily, provided not more than 0·3 gramme of PbS is taken. Two molecules of ferrous sulphate result from the oxidation of one of lead sulphide. In the case of bismuth sulphide, which is attacked with great ease, the proportion is $Bi_2S_3 = 6FeSO_4$. F. H. L.

Solubility of the Bicarbonates of Calcium and Magnesium. F. P. Treadwell and M. Reuter. (*Zeits. anorg. Chem.*, 1898, xvii., 170.)—This article contains an account of various experiments on the bicarbonates of the alkaline earths which were carried out to determine whether these compounds actually exist as such, and also to estimate their solubility in water in the presence or absence of free carbon dioxide. The results given briefly are: Calcium bicarbonate does exist as such in aqueous solution, its solubility at 15° C. and average atmospheric pressure being 0·385 gramme per litre. The solubility of calcium bicarbonate is not appreciably affected by dilute (decinormal) solutions of common salt. Magnesium bicarbonate does not exist in solution except in the presence of free carbon dioxide; in the absence of the gas it breaks up into a mixture of normal carbonate and bicarbonate, until the liquid, at the above temperature and pressure, contains 0·7156 gramme of the former and 1·954 gramme of the latter per litre. F. H. L.

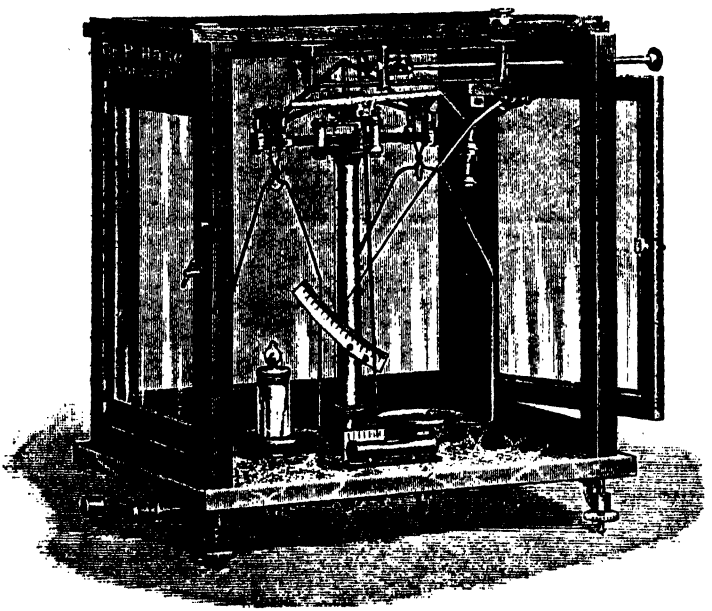
APPARATUS.



An Apparatus for the Analysis of Calcium Carbide. H. Bamberger. (*Zeit. angew. Chem.*, 1898, 243.)—This is recommended for the simple and accurate valuation of calcium carbide by a method combining the author's gravimetric process (ANALYST, this vol., p. 167) with the gas-volumetric process of Fuchs and Schiff (ANALYST, this vol., p. 25).

The flask A, which serves as a gasometer, contains 20 litres, and is graduated into decilitres. It is connected with a similar flask, B, and is nearly filled with a concentrated solution of sodium chloride, saturated with acetylene at the ordinary temperature. The gas is generated in the gravimetric flask, C, and drives the brine forward into B. When the reaction is over, the liquids in both flasks are brought to the same level, and the amount of acetylene read off and corrected for temperature and pressure (*cf.* ANALYST, this vol., p. 25).

The apparatus can be obtained from Max Kähler and Martini, Berlin, W.



C. A. M.

Apparatus for the Delivery of Small Quantities of Mercury (for Nitrogen Determinations). R. Meyer. (*Chem. Zeit.*, 1898, xxii., 331).—As shown in the accompanying illustration, this apparatus serves for the storage of about 250 grammes of mercury in the bulb *a*, and also for the delivery of a definite amount of the reagent such as is required in a Kjeldahl nitrogen estimation. When the hemispherical depression in the stopcock *c* is in a vertical position it fills with mercury from the reservoir, and when it is rotated till opposite the exit tube *d* the mercury runs out, its place being taken by air entering through *e* and the groove in the cock. *e* also catches any drops that may escape out of the groove while the hole is being filled.

F. H. L.

An Improved Analytical Balance. (*Chem. Zeit.*, 1898, xxii., 540.)—This apparatus consists essentially of a short-beam analytical balance, which, in order to gain an approximate idea of the weight of any substance placed in the pan, can be temporarily put in connection with a spring-balance by means of the knob seen projecting from the top of the case in the accompanying illustration. When the spring-balance is in gear, the long lever shows the weight of the substance on the curve scale to the nearest deci- or centigramme; and, after it has been thrown out, the correct weights can usually be placed at once on the opposite pan, leaving only the rider of the balance proper to be manipulated. The convenience of this arrangement is apparent, and it will be specially appreciated in weighing out exact quantities of things, for during the whole process the arresting-gear of the true balance need not be used at all (see also ANALYST, xxi., 248).

F. H. L.

THE ANALYST.

OCTOBER, 1898.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE PROPORTION OF OXYGEN PRESENT IN LINSEED-OIL, BOTH BEFORE AND AFTER OXIDATION.

By Rowland Williams.

(Read at the Meeting, June 1, 1898.)

The elementary composition of raw linseed-oil is stated by W. T. Brannt ("Animal and Vegetable Fats and Oils," p. 273) to be as follows:

	C.	H.	O.
Cold-drawn	78·11	10·96	10·93
Hot-pressed	75·27	10·88	13·85

In Allen's "Commercial Organic Analysis," vol. ii., p. 118, I find the following figures for linseed and poppy oils respectively, the results of the linseed-oil being those of three observers:

Observer.	Kind of Oil.	C.	H.	O.
Sacc	Linseed	78·11	10·98	10·93
König	,,	77·40	11·10	11·50
Clöez	,,	77·57	11·33	11·10
,, ...	Poppy	77·50	11·40	11·10

After eighteen months' exposure the two last samples gave:

Clöez	Linseed	72·27	10·57	24·16
,, ...	Poppy	71·38	10·64	25·08

These figures indicate comparatively little difference between linseed and poppy oils, either in the raw state or after "drying."

About a year ago I was engaged upon a research, in the course of which it was necessary to submit to ultimate analysis several samples of linseed-oil, some raw and others after boiling and oxidizing in various ways. The results are given in the table below:

	Raw.		Boiled.				Solid.			
	1.	2.	3.	4.	5.	6.	7.	8.	9.	10.
C. ...	75·03	75·40	74·66	74·32	69·74	69·52	64·74	65·40	68·64	64·38
H. ...	10·78	10·64	10·38	10·04	9·57	9·49	9·01	9·00	9·24	9·01
O. ...	14·19	13·96	14·96	15·64	20·69	20·99	26·25	25·60	22·12	26·61

The figures in the first two columns were obtained from raw linseed-oil, those in the third from moderately stout boiled oil. All the other figures refer to samples of solid oil, such as is used in the manufacture of linoleum. Sample 4 was made by one method, 5 by another, samples 6 to 9 by a third process, and 10 by a fourth.

As will be observed, sample 4 contains very much less oxygen than any of the other samples of solid oil. It is interesting to notice that the samples marked respectively 8 and 10 gave fairly similar results, although the oils were made by entirely distinct methods.

NOTE ON CERTAIN RESINS.

By Rowland Williams.

(*Read at the Meeting, June* 1, 1898.)

Some years ago I made an investigation of a number of resins and gums, the results of which are recorded in the *Chemical News*, vol. lviii., pp. 224, 225. I have recently examined, on somewhat similar lines, samples of kauri, copal, and dammar, representing large stocks of these particular resins. The chief point of interest about the present samples lies in the fact that the kauri and one of the copals were examined not only in their original condition, but also after being subjected to the melting or "running" process, which is applied to certain resins previous to converting them into varnish.

	Kauri.		Copal.			Dammar.
			Fine Quality.		Finest.*	
	Ordinary Condition.	After "Running."	Ordinary Condition.	After "Running."	Ordinary Condition.	Ordinary Condition.
	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.
KOH absorption, hot	6·42	5·16	18·87	13·78	12·87	2·85
,, ,, cold	6·19	4·76	14·36	10·99	11·56	2·63
Iodine absorption ...	130·62	126·52	124·32	129·60	95·40	99·40
Loss or gain on heating at 100° C. for fifteen hours ...	11·81 loss	0·80 gain	0·82 loss	2·26 gain	0·74 loss	0·84 loss
Mineral matters ...	0·15	0·14	0·14	0·16	0·03	0·05

As would be anticipated, the resins in their original state lost weight on heating at 100° C.—the kauri to a considerable extent, the others only slightly. It is interesting to observe, however, that the two resins which had been fused, when heated under the same conditions, gave a decided increase in weight, especially the copal, pointing to a certain amount of oxidation having taken place. It may be well to mention that the hot KOH determinations were made according to Koettstorfer's method, but, as some resins are rather difficult to attack completely, a very large

* This is an exceptionally fine quality of copal, used only in the manufacture of the palest and highest class of varnishes.

excess of alcoholic KOH was added, and the boiling continued for a much longer time than usual.

The cold KOH determinations were made by digesting the finely powdered resins with a mixture of ether and alcohol, and titrating with $\frac{N}{2}$KOH, using phenolphthalein as indicator. The percentages of iodine absorbed were estimated as in the case of oils and fats, a large excess of Hübl's reagent being allowed to act all night (sixteen hours).

EXPERIMENTS ON THE EFFECT ON BUTTER OF FEEDING COTTON-SEED AND SESAME OILCAKE.

(*Reprinted from the Annual Report on the Distribution of Grants for Agricultural Education and Research in the year* 1897-98.)

EXPERIMENTS on behalf of the Board of Agriculture were undertaken during the present year by the South-Eastern Agricultural College, at Wye, for the purpose of determining whether, and to what extent, the substances giving the cottonseed and sesame oil reactions might be found in the butter made from the milk of cows fed on cottonseed and sesame oilcakes.

The following report on the results of the experiments has been drawn up by Dr. T. E. Thorpe, F.R.S., the principal chemist of the Government Laboratories.

The experiments were carried out as follows:

Twelve cows (particulars of age, breed, etc., are given in Appendix A) were divided into three sets of four. Commencing on the 16th of February last, all the cows were fed with the standard ration described in Appendix B, together with 4 lbs. of linseed oilcake each per day. This feeding was continued till the 19th of March. Milk was taken at intervals of a day or two from each cow, and made into butter under the supervision of the Principal of the Wye College. Samples of the butter were forwarded to the Government laboratory, where they were examined for the cotton-seed and sesame oil reactions. The results of the tests were uniformly negative; and it having been established that none of the cows gave any indications of cotton-seed or sesame reactions in the absence of the cake, the feeding with cotton and sesame cake was commenced. On the 19th of March one half the daily allowance of linseed oilcake was replaced by a similar amount of cottonseed oilcake in the case of the first set of cows (Nos. 1 to 4), and by sesame cake in the case of the second set (Nos. 7 to 10), the third set (Nos. 5 and 6, 11 and 12) being continued on the linseed cake as before for purposes of comparison.

On the 20th of March samples were obtained from each cow as before. On the examination of the butter, the samples from the first set of cows (Nos. 1 to 4) gave a distinct reaction for cottonseed-oil by two tests. No such reaction was given by any of the other samples, nor was any reaction for sesame-oil given by the samples from any of the cows. Samples taken at intervals during this period gave similar results. On the 28th of March the linseed cake was entirely replaced by cottonseed cake and sesame cake in the case of the first and second sets of cows respectively. This

feeding was continued up to and including the 18th of April, samples being taken from each of the cows Nos. 1 to 10 daily, and from 11 to 12 at longer intervals.

Every sample from the four cows fed on cottonseed cake gave the reaction for cottonseed-oil, while the others gave negative results. Neither in the samples from the cows fed on sesame cake, nor in any of the other samples, was any indication of the sesame-oil reaction found.

As no marked increase in the intensity of the cottonseed-oil reaction was apparent at the end of the month's feeding on the normal ration of 4 lbs. of cake, the quantity, in the case of the first set of cows (Nos. 1 to 4) was gradually increased to 6 lbs., and then to 7 lbs. per day, which was found to be about the maximum amount the cows would eat. This feeding was continued till the 24th of May; but, even after more than two months' feeding with cottoncake, the results of the examination of the butter showed no decided or general increase in the cottonseed-oil reaction.

From the 24th of May also the cows numbered 7 and 8 had their sesame cake gradually replaced by cottonseed cake. Samples taken less than twenty-four hours after they had received 2 lbs. of cottoncake gave the cottonseed-oil reaction, and subsequent samples gave similar results. In the case of the samples from cows Nos. 9 and 10, taken on the 26th of April and the 3rd of May, a slight cottonseed-oil reaction was observed, although the cows were apparently receiving no cottoncake. On investigation, however, it was found that a small quantity of broken cottoncake had accidentally got mixed with the chopped straw from which the cows were being fed.

The daily allowance of sesame cake was in a similar way increased to 7 lbs. (the cows would eat no more) in the case of cows Nos. 9 and 10, but no sesame-oil reaction was obtained in any of the samples from these cows even at the end of two months.

On the 25th of May the cake feeding was discontinued and the cows turned out to grass. On the 26th of May, and about every alternate day till the 17th of June, samples were taken from the first set of cows (Nos. 1 to 4), and the results of their examination showed that the cottonseed-oil reactions persisted in a distinct form for about three days, and were distinguishable in the butter from three out of the four cows on the fifth day. At the end of a week it had disappeared from all.

In a number of samples the reactions given by the tests for cottonseed-oil were carefully compared with those given by similar butterfats to which 1, 2, and 5 per cent. of four representative samples of commercial cottonseed-oils had been added. From a comparison of the results of the tests, it was apparent that the strongest reactions from the samples from the cows fed on cottonseed cake did not much exceed that given by 1 per cent. of cottonseed-oil added to butter, and the great majority of the samples gave reactions indicating less than 1 per cent.—reactions which would, indeed, be almost obscured in butter prepared and coloured in the ordinary manner.

On several occasions the Principal of the College prepared butter in the ordinary way from the mixed milks of the cows in the respective sets. The results of the examination of samples of these butters were similar to those from the individual cows, the intensity of the cottonseed-oil reaction being intermediate between the weakest and strongest cows in the set. These butters were, however, uncoloured, and the reactions were consequently not obscured.

The individual cows seemed to vary somewhat in their ability to pass the reacting substance into the milk fat—cow No. 2 giving uniformly less intense reactions than the others.

It also appears that, whilst in the butter from cows fed on linseed oilcake there is a tendency for the analytical results to vary towards those given by margarine, the tendency in the case of sesame and cottonseed oilcake feeding is in the opposite direction.

The general conclusions to be drawn from these experiments may be summed up as follows:

1. Cows fed on cottonseed oilcake produce milk the butter-fat of which gives cottonseed-oil reactions.

2. The reactions appear when the cows receive only a small quantity of cake. They increase somewhat with continuous feeding, but apparently cannot be carried beyond a certain point, even when the amount of cake is increased to the full limit which the cows under ordinary circumstances care to eat.

3. The reacting substance passes into the milk within less than twenty-four hours after the cake-feeding begins, and continues to do so for several days after it has been dropped.

4. The reactions vary in intensity in individual cows, but do not in any case much exceed those given by 1 per cent. of cottonseed-oil mixed with butter. The presumption is, therefore, that in butter made in the ordinary way from the mixed milks of several cows, the reaction would, as a rule, be less than that due to the presence of 1 per cent. of the oil, and experiment shows that this is actually the case.

5. As feeding with cottonseed oilcake gives butter affording analytical data tending to differ from, rather than to approach to, those given by margarine, it appears to be possible in most cases to differentiate between the cottonseed-oil reaction due to feeding on cottonseed oilcake and that produced by any considerable admixture of margarine containing cottonseed-oil with butter.

6. The butter from the milk of cows fed on sesame oilcake gives no sesame-oil reaction, even after more than two months continuous feeding up to as large a quantity as the cows will take.

Similar results have been obtained by other observers.

Dr. Stein (*Tiddskrift for Landökonomi*, 1894, 664) came to similar conclusions both in his cottonseed and sesame oilcake feeding experiments. Two cows only were employed.

In Dr. Werenskjold's experiments (private communication), made on the mixed milk of two groups of four cows each, the cottonseed-oil reaction was apparent.

Harrington and Adriance (*U.S.A. Exp. Station Record*, vol. vi., 323) obtained similar results from two cows fed on cottonseed-meal.

Recent experiments made by E. Ramm and W. Mintrop, at the Poppelsdorf Agricultural Academy, under the instructions of the German Imperial Health Department (*Milchzeitung*, No. 17, April 23, 1898), with sesame cake and sesame-oil feeding gave entirely negative results with the sesame-oil test.

Dr. M. Siegfeld (*Milchzeitung*, No. 21, May 2, 1898) in a similar series of experiments obtained some positive results. With one exception, however, the intensity of

the reactions was very weak—equivalent to only a few hundredths per cent. of sesame-oil; and as similar reactions were given by some butters from cows not fed on sesame cake, the results cannot be considered as very trustworthy. Dr. Siegfeld makes a point of heating the mixture during the test, which is certainly desirable; but great care is necessary, otherwise a pinkish colour may be produced which might be mistaken for the sesame-oil reaction.

During the whole of Periods I. to V. all the cows had daily, in addition to the

cake, a ration consisting of 4 lbs. dried grains, 2 lbs. bean meal, 25 lbs. hay and chopped straw, and 40 lbs. root (swedes and mangolds).

The bean-meal and part of the grains were withdrawn from cows 1 to 4 and 7 to 10 towards the end of Period IV.

FOODS AND DRUGS ANALYSIS.

Gottlieb's Method for estimating Fat in Milk. **M. Weibull.** (*Chem. Zeit.*, 1898, xxii., 632.)—The apparatus in which this process is carried out consists of a glass tube about 40 cm. long, sealed at one end, and provided with marks at the points where it holds 70·5 c.c. and 19·0 c.c., or else graduated regularly between the 16 and 20 c.c. positions. Into it is measured exactly 10 c.c. of milk (equal to 10·27 grammes), 1 c.c. of 20 per cent. ammonia is run in from a burette, and then 10 c.c. of 95 per cent. alcohol. The liquid is shaken, 25 c.c. of ether introduced, the tube closed with a damp cork, and inverted several times. Twenty-five c.c. of petroleum spirit are next added to remove water, sugar, etc., from the ether, and after the whole has been thoroughly agitated, it is allowed to rest until the liquids have separated perfectly. In the case of milks poor in fat, the line of division is exactly at the 17·5 c.c. point (when there is one); then the ethereal liquid is syphoned off down to the 19 c.c. mark (leaving 1·5 c.c. behind, and yielding a solution containing the fat in 10 grammes of milk), evaporated or distilled, dried for two hours at 100° C., and weighed. The petroleum spirit should boil below 80°, and both it and the ether must be free from fixed residue, but the latter need not be dry. If the original sample is sour, it is treated with exactly 10 per cent. of ammonia, and 11 c.c. (equal to 10 c.c. of milk) are measured off. Buttermilk sometimes contains membranous substances which adhere to the walls of the tube and pass through the syphon, contaminating the fat solution. This may be avoided by the addition of 10 per cent. of ammonia as before, taking 10 c.c. for analysis, and adding 10 per cent. to the figures obtained. Provided the recovered fat forms a perfectly clear oil when taken out of the drying oven, and that it is soluble in a very small volume of dry ether, it must be pure and free from foreign matter; and accordingly, if Gottlieb's process gives higher results than other methods, this is simply due to its superior accuracy.

In order to compare the kaolin and paper gravimetric processes with the present one, four specimens of milk were prepared and submitted to ten different analysts. Nos. I. and II. of these samples were separated milk; III. a full milk, all containing a trace of formalin; IV. was a buttermilk mixed with 10 per cent. of ammonia to ensure uniformity of composition. The subjoined table shows the average amount of fat contained in each material, as deduced from the single results of the various investigators, and as returned by the three different processes; it also records the

greatest difference from the mean found by any individual observer; while as a few of the tests were admittedly bad, the last column gives the corrected differences from the mean after the worst results have been rejected:

		Average Percentage of Fat.	Maximum Difference.	Corrected Difference
Kaolin process	I. ...	0·109	±0·036	±0·024
	II. ...	0·240	0·050	0·030
	III. ...	3·562	0·038	0·038
	IV. ...	0·340	0·070	0·028
Paper process	I. ...	0·083	0·023	0·023
	II. ...	0·239	0·021	0·021
	III. ...	3·542	0·082	0·082
	IV. ...	0·268	0·038	0·088
Gottlieb's process	I. ...	0·115	0·010	0·010
	II. ...	0·263	0·027	0·010
	III. ...	3·533	0·043	0·043
	IV. ...	0·350	0·022	0·022

Summing up the whole case, it would appear that with skim milk and buttermilk Gottlieb's process yields the most concordant results; but for the examination of full milk there is nothing to be chosen between the three methods. And although the investigation has not yet proceeded far enough to prove definitely that the figures given by the former are nearest the truth, nevertheless its greater uniformity in the hands of different chemists strongly points in that direction. The comparative failure of the process in the analysis of milks rich in fat simply depends on the fact that the line of division between the ethereal and aqueous liquids in the tube does not stand quite at the 17·5 c.c. point—because the percentage of fat being higher, that of the milk-serum is smaller—so that the volume of fat solution withdrawn does not correspond exactly to 10 grammes of milk. This may be overcome by graduating the whole of the tube, noting the volumes after separation, and evaporating the proper quantity of the ethereal liquid. Gottlieb's method is certainly simpler and cheaper to carry out than either of the others. F. H. L.

The Calculation of the Calories of Combustion in Oxygen of Cereals Calculated from Analytical Data. H. W. Wiley and W. D. Bigelow. (*Journ. Amer. Chem. Soc.*, 1898, xx., 304-316.)—As the determination of the heat of combustion is now often made in the analysis of food products, and especially when information is required as to their dietetic value, the authors have made experiments to determine to what extent the calorimetrical results, as determined by the bomb calorimeter, agree with those calculated from the different constituents of the food.

The three main constituents in cereals are carbohydrates, proteids, and oils, while there are smaller amounts of other substances, such as amides, organic acids, lecithins, and colouring matter, which collectively evolve a considerable quantity of heat on combustion.

The different classes of compounds grouped under the term of carbohydrates show considerable variations in calorific power. In round numbers the heat value of the pentoses (arabinose, xylose), and of lactose (crystallized), dextrose, and fructose, is 3,750; of sucrose, maltose, and lactose (anhydrous), 3,950; and of starch

and cellulose 4,200 calories per gramme. The value of the pentosans is about 50 calories greater than that of the pentoses, and their factor is therefore 3,750 + 50 = 3,800.

In the absence of more reliable information on the results of the combustion of different proteid substances, the authors have adopted the factor 5,900 calories per gramme as being the one most generally correct. They consider it the best to determine the non-proteid nitrogen and to use this factor for the residual proteids. Asparagine may be taken as a representative vegetable amide, and the factor for asparagine is 3,400 calories per gramme.

The following example is given of the use of these data in the computation of the heat value of the nitrogenous constituents of cereals: A sample of wheat-flour was found to contain 10·71 per cent. of proteids and 0·48 per cent. of amide bodies calculated as asparagine. The calories of combustion were calculated as follows:

	Calories.
0·1071 gramme proteids × 5,900 = ...	631·9
0·0048 gramme asparagine × 3,400 = ...	16·3
Total calories due to nitrogen compounds ...	648·2

The oils extracted from different cereals and purified in the usual manner gave the following results on combustion in calories per gramme: Wheat-oil, 9,359; rye-oil, 9,322; maize-oil, 9,280. The nearest round numbers for these would be 9,350 for the wheat-oil and 9,300 for the other two. But since in calculating from the analytical data the ethereal extract contains other substances beside oil, the authors have determined the heat of combustion per gramme of the extract of several cereals. In round numbers these were: Wheat, 9,100; oats, 8,950; barley, 9,100; and rye, 9,200. In order to make allowance for the small amounts of colouring matter, organic acids, and other substances not included in the foregoing data, they propose to use the general factor 9,300 for the multiplication of the ethereal extract, both of flours and meals and of baked products.

The following tables give the calorific results calculated from the analysis in comparison with those determined by direct combustion:

Chemical Composition of Samples of Grain.

	Wheat, No. 1. Per Cent.	Wheat, No. 2. Per Cent.	Rye. Per Cent	Unhulled Oats. Per Cent.	Hulled Barley. Per Cent.

Totals ...	3,938	4,016	3,861	4,002	3,847

The fact that the calculated calories were 179 lower than those directly determined in the case of the unhulled oats suggests the possibility that the heat of combustion of the unidentified carbohydrates of hulls and fodders is greater than that of starch. The authors consider that the direct combustion and the analysis should afford a check as to the correctness of each. At present they regard the check as satisfactory when the difference between the observed and calculated calories does not exceed 50 to 75.

In the following table of the comparative results obtained with various substances, the proteid has been calculated from the nitrogen by the factors 5·70 and 6·25:

The authors are investigating the data for the calculation of heat of combustion in bodies rich in ligno-cellulose, etc., such as bran, hay, and fibres generally, and promise a further communication on the subject. C. A. M.

Detection of Sawdust in Flour. G. A. Le Roy. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 505.)—Sawdust can be detected in common descriptions of flour by means of an alcoholic solution of phloroglucinol strongly acidified with phosphoric acid. On gently warming, the particles of sawdust acquire a strong carmine-red colour, whereas the bran particles of the cereals are at first scarcely affected at all. H. H. B. S.

A Substance other than Sugar in Fruit Juices capable of reducing Fehling's Solution. Aderhold and Heintze. (*Chem. Zeit.*, 1898, xxii., 632.)—In estimating the proportion of sugar in the juice of cucumbers by means of Fehling's solution, the authors recently obtained very different results when the liquor was expressed from the fruit in its natural condition from those yielded by the aqueous extract of the cucumbers after they had been previously dried. On adding a moderate amount of alcohol to the neutral juice, a gelatinous flocculent precipitate was produced, which appeared to be a pectin, and did not reduce Fehling's solution; but on filtering the liquid and adding more alcohol a yellowish-brown, resin-like body was thrown down, which exhibited powerful reducing properties. It was readily soluble in water, had a sharp, not a sweet taste, and entirely lost its reducing power when its aqueous solution was evaporated and the residue dried on the water-bath for several hours. This peculiarity no doubt explained the anomalous behaviour of the fresh cucumber juice; for hitherto the new body has always been returned as a sugar when Fehling's process is made use of. The same substance has been detected in strawberries, bilberries, gooseberries, and cherries, and probably exists in all fruits, in which, when ripe, the proportion is small. In green apples, however, it is considerable. F. H. L.

The Determination of Malic Acid in Grape Juice. A. Girard and Lindet. (*Bull. Soc. Chim.*, 1898, xix., 585.)—The tartaric acid (free and combined) is first determined as tartar by the method of Berthelot and Fleurien, in which the hydrogen potassium tartrate is precipitated by a mixture of alcohol and ether, and the free tartaric acid by saturating about one-third of the liquid (containing the ether) with potash, and adding the remaining two-thirds.

After removal of the tartaric acid the alcohol and ether are expelled by evaporation, and a solution of normal lead acetate added to the boiling aqueous solution until there is a permanent turbidity. The boiling liquid is filtered, and the lead malate allowed to crystallize. The next day the mother liquor is treated in the same way, the lead malate collected, and the process again repeated, and so on until no more crystals are deposited on cooling. The lead malate is then dried, detached from the filter, and weighed.

Since lead malate is soluble to some extent in acetic acid, a correction must be made at the end of the determination for the amount of free acid in the mother liquid. This can be done by means of the following table:

Quantity of free Acetic Acid in 100 c.c. of Mother Liquid.	Lead Malate dissolved in 100 c.c. of Mother Liquid.
0·21	0·10
0·40	0·13
0·55	0·16
0·73	0·18
0·90	0·20

The authors state that test experiments with this method have given satisfactory results. C. A. M.

On the Recognition of White Wines prepared by the Decolorisation of Red Wines. A. Bimm. (*Journ. Pharm. Chim.*, 1898, viii., 9-11.)—When white wine has been prepared by the decolorization of red wines by means of animal charcoal, the author finds that the sophistication can often be detected in the following manner:

A solution of diphenylamine is prepared by dissolving 0·1 gramme in 100 c.c. of sulphuric acid (1 : 4), and making up the volume to 500 c.c. with sulphuric acid of 66°. To 2 c.c. of this reagent in a porcelain dish 6 drops of the wine are added, and if a blue coloration is obtained, it points to the wine being a decolorized red wine. The author has obtained this reaction with a large number of white wines, which, from the results of the analysis, were suspected of being decolorized products. With some of these the colour was partially restored on the addition of hydrochloric acid. On the other hand, the blue coloration did not appear in the case of white wines of authentic origin and normal composition.

The substance which causes the blue colour was found to be a usual constituent of animal charcoal, which dissolves in the wine and gives the reactions of a nitrate.

C. A. M.

Studies on the Products obtained on Roasting Coffee. H. Jaeckle. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 457.)—The products were collected by means of a condenser cooled by ice attached to the coffee-roaster. The distillate was a brownish-yellow fluid having the aroma of freshly-roasted coffee and a bitter sour taste. The following products were identified, viz., acetone, furfurol, caffeine, ammonia, trimethylamine, formic acid, acetic acid (resorcin). Of these products, caffeine, furfurol, and acetic acid were found in somewhat considerable quantities; but acetone, ammonia, trimethylamine, and formic acid in only very small proportions. Bernheimer's "caffeol" could not be detected. That caffeine was found in the distillate accords with the recent observation that coffee sustains a loss of caffeine in roasting.

H. H. B. S.

A New Method of Sophisticating Coffee. T. F. Hanausek. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 399.)—The author remarks that the practice of centrifuging coffee-berries with sawdust to improve their appearance, referred to by Wirtz (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 248; ANALYST, 1898, this vol., 209), has been carried on for several years. He considers it questionable that it is done with the object of imparting a fine white to the furrows, as stated by Wirtz, and believes the object is merely the removal of the mottled appearance due to the outer skin, and the imparting of more or less polish to the berries. He, therefore, disagrees with Wirtz in considering the practice as equivalent to adulteration, though he would prefer to see the sawdust completely removed. The practice of colouring coffee-berries is, however, in the author's opinion, quite another matter, and he proposes to deal fully with this in a future paper.

H. H. B. S.

The Detection of Gelatin in Chocolate. P. Onfroy. (*Journ. Pharm. Chim.*, 1898, viii., 7-9.)—By the addition of 5 per cent. of gelatin it is possible to introduce at least 10 per cent. of water into a chocolate without altering the appearance of the latter. A sample of chocolate thus adulterated gave the following percentage results on analysis: Ash, 2·72; sugar, 46·17; fat, 14·24; water, 12·20. Twenty-five grammes of this product when mixed with hot water gelatinized on cooling.

The results obtained with five samples of chocolate manufactured by reliable makers were:

		Per cent.				
Ash	...	1·07	1·46	1·36	2·21	1·69
Fat	...	21·60	19·90	21·05	19·60	20·50
Sugar	...	63·99	63·18	60·75	59·94	61·56
Water	...	0·98 to 2·50				

As a positive test for gelatin 5 grammes of the suspected chocolate are treated with 50 c.c. of boiling water and 5 c.c. of a 10 per cent. solution of lead acetate added. The liquid is filtered, and several drops of a saturated aqueous solution of picric acid added to the filtrate. In the presence of a notable quantity of gelatin a yellow precipitate is obtained.

When the gelatin is only present in traces, the tannin in the cocoa combines with it, forming an insoluble precipitate, which remains on the filter. In such cases 10 grammes of the chocolate are extracted with ether to remove the fat, the residue treated with 100 c.c. of hot water, and the liquid filtered after the addition of 5 to 10 c.c. of a 10 per cent. solution of potassium hydroxide and 10 c.c. of the lead acetate solution. The filtrate is exactly neutralized and tested for gelatin in the usual way.

These tests are only qualitative, but an approximate idea of the quantity of gelatin present can be calculated from the amounts of the other constituents.

C. A. M.

Utilization of Cacao-husks. G. Paris. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 389.)—Cacao-husks are now finding a much more extended use than was formerly the case. The roasted husks, on account of their aroma, are readily eaten by cattle, and may be advantageously given in conjunction with other foods. They are also used for the preparation of cheap beverages. Treated after the manner of tea, they yield an extract of a bitter flavour, which, on the addition of sugar and milk, is used as a substitute for coffee or chocolate.

According to the author's analysis, the following is the percentage composition of roasted husks:

Water.	Nitrogenous Matter.	Fat.	Non-nitrogenous Extractial Matter.	Crude Fibre.	Ash.
12·57	14·69	3·30	45·76	16·33	7·35

A decoction of 50 grammes of the powdered roasted husks in hot water diluted after cooling to 500 c.c. yielded the following results upon analysis:

		Per Cent.				
Sp. Gr. at 15° C.	Extract.	Organic Matter.	Ash.	Reducing Sugar (Dextrose).	Theobromine.	Acid (Tartaric).
1·1269	25·08	20·68	4·40	0·21	0·79	0·12

The presence of cacao-husks in cocoa-powder may in most cases be detected microscopically by the annular, spiral, and small hexagonal cells of the husks and the characteristic table-shaped cells of the epidermis. H. H. B. S.

A New Pepper Adulterant. T. F. Hanausek. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 490.)—A sample of ground pepper from Prague was found to contain foreign particles not corresponding with any of the substances usually employed for mixing with pepper. Three special peculiarities were observable: (1) bundles of corrugated bent fibrous cells; (2) coarse parenchyma overlaid with narrow cells of a yellow colour with parallel walls; and (3) colourless cellular parenchyma, firm in the walls and enclosing numerous beautiful crystal rosettes and granules. The two last peculiarities were recognised as characteristic of a fruit of the order Umbelliferæ, the bundles of fibres as well as the absence of vittæ (oil cavities) pointed to coriander, and a comparison with the structure of this fruit showed without doubt that the pepper had been adulterated with ground coriander-seeds. H. H. B. S.

Adulteration of Vanillin in Switzerland. R. Hefelmann. (*Apoth. Zeit.*, 1898, xiii., 420; through *Chem. Zeit. Rep.*, 1898, 181.)—A sample of vanillin supplied by Ewald and Börlin, of Basle, was recently examined, and found to contain about 26 per cent. of acetanilide. F. H. L.

Physiological Action of Copper. Baum and Seeliger. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 500; from *Zeit. öffent. Chem.*, 1898, 181.)—The authors have carried out a large number of experiments upon animals extending over a period of three years. The following are some of the principal results arrived at:

Copper absorbed into the system through the digestive organs does not, as a rule, pass into the milk. Occasionally it is found in minute traces in the milk, but only quite exceptionally in weighable amounts. No injurious consequences could be traced to the use of milk produced by animals that had been dosed for long periods with copper, not even when the milk was used as an exclusive diet, as, for example, or suckling.

Copper absorbed into the system through the digestive organs passes in proportionate quantity into, and is stored in, the fœtus.

When administered in small daily doses, copper is, as a rule, all absorbed, and for the most part all again eliminated. When increased quantities are given, however, no more is absorbed—often, indeed, less. The absorption and elimination, therefore, does not appear to proceed with regularity or to follow any decided rule.

The elimination of the copper through the bile and pancreatic and intestinal juices may take as much as five months from the time the administration was discontinued, though it may be complete in four or five weeks. By long-continued administration of small doses of copper a really chronic poisoning may be produced.

Different copper preparations possess poisoning properties in different degrees.

H. H. B. S.

Contribution to our Knowledge of Pilocarpidine. J. Herzig and H. Meyer. (*Monatshefte für Chemie*, 1898, xix., 56.)—The authors discuss the subject of the assumed identity of Merck's pilocarpidine from jaborandi-leaves with the supposed pilocarpidine of Hardy and Calmels, Petit and Polonowski, produced from pilocarpine. They had already pointed out (*Monatshefte für Chemie*, xviii., 382) that the evidence of identity was insufficient, and they now show by means of the determination of methyl that they are able to completely corroborate Merck's conclusion, arrived at in a different way, thus placing the non-identity of these bodies beyond question. As additional proof, the authors have made methyl determinations in the double salts of gold of these bodies, and give the following results:

PILOCARPIDINE DOUBLE SALT WITH GOLD.

	Found.		Calculated for $C_{10}H_{14}N_2O_2$, HCl, $AuCl_3$
	I.	II.	
Au	36·75	—	36·85
CH_3—N	—	0·19	2·81

CONVERTED PILOCARPINE DOUBLE SALT WITH GOLD.

	Found.		Calculated for $C_{11}H_{16}N_2O_2$, HCl, $AuCl_3$
	I.	II.	
Au	35·85	—	35·72
CH_3—N	—	3·07	2·74

H. H. B. S.

Contributions to our Knowledge of the Alkaloids of Macleya Cordata. K. Hopfgartner. (*Monatshefte für Chemie*, xix., 179.)

ALKALOID I. (*Macleyine, Protopine*).

The melting-point of the free base was given by Eykman as 201° C. Selle, however, gave the melting-point of a base obtained from *Chelidonium majus*, the identity of which with macleyine is in the highest degree probable, as 207° C. The author at first found the melting-point of the free base to be 202° to 203° C., but subsequent determinations, after repeated crystallization from alcohol, gave 207° C. The following is supplementary to Eykman's description of this alkaloid: The base is difficultly soluble in carbon bisulphide and benzene, and very difficultly soluble in petroleum spirit. It crystallizes best from a mixture of alcohol and chloroform, in colourless, lustrous, four-sided prisms. The reactions with sulphuric acid were found to agree with the description given by Eykman. Zeisel's method for the determination of methoxyl gave negative results. Determinations of carbon and hydrogen corresponded with the formula $C_2H_{19}NO_5$. The base is optically inactive. The nitrate is a white powder which is seen to be crystalline when observed under the microscope. It is difficultly soluble in cold water, but more so in hot, from which it crystallizes out on cooling. Determinations of carbon and hydrogen corresponded with the formula $C_{20}H_{19}NO_5$, HNO_3.

The hydrochloride separates out in six-sided prisms on neutralizing the base with

hot dilute hydrochloric acid and cooling. It is soluble in alcohol and with some difficulty in cold water. Its analysis corresponded with the formula

$$C_{20}H_{19}NO_5, HCl + \tfrac{1}{4}H_2O.$$

ALKALOID II.

This is obtained in the form of nitrate from the mother-liquor of the protopine nitrate crystallization, from which the base is precipitated by potash as a white amorphous powder, which after long standing under the fluid becomes gradually crystalline. The crystallized base dissolves easily in chloroform, less easily in alcohol, carbon bisulphide, benzene, and acetic ether, and still less in ordinary ether. Its composition agrees with the formula $C_{21}H_{23}NO_5$. Zeisel's method revealed the presence of two methoxyl groups. The base is optically inactive. The nitrate of base II. is a colourless salt, soluble in alcohol, and moderately difficultly soluble in cold water. Determinations of carbon, hydrogen, and water agreed with the formula

$$C_{21}H_{23}NO_5, HNO_3 + 1\tfrac{1}{2}H_2O.$$

Dried at 100° C., its formula is

$$C_{21}H_{23}NO_5, HNO_3 + \tfrac{1}{4}H_2O.$$

The hydrochloride crystallizes out in the form of fine white needles on cooling a solution of the free base in hot dilute hydrochloric acid. Its composition corresponds to the formula

$$C_{21}H_{23}NO_5, HCl + 1\tfrac{1}{2}H_2O.$$

Dried at 100° C., its formula is

$$C_{21}H_{23}NO_5, HCl + \tfrac{1}{2}H_2O.$$

There is also a double salt of platinum of the formula

$$(C_{21}H_{23}NO_5, HCl)_2PtCl_4.$$

H. H. B. S.

Oil of Cade. P. Adam. (*Bull. Soc. Chim.*, 1898, xix., 580-583.)—This oil is largely employed as a therapeutic agent in certain diseases of the skin. The pure product has been examined by Hirschsohn (*Pharm. Zeit. f. Russ.*, 1895, xxxiv., 817) and by De Schulz (*Arch. de Sc. Viol. St. Petersburg*, 1897, 345-374), and the author's researches have been carried out with the sole purpose of determining whether it was possible for a pharmacist to obtain an oil answering to the requirements of the French Codex.

The different specimens examined were supplied by reliable French firms, and were tested in accordance with Schulz's directions. On treatment with caustic potash all absorbed oxygen with great rapidity from the air. They were fractionated by distilling 300 grammes under the ordinary pressure, and each fraction was dissolved in ether and shaken with a solution of an alkaline carbonate to remove the free acids. The ethereal layer was then shaken with a solution of caustic potash, which dissolved the phenols and polyphenols, leaving the phenol esters, ketones, and other neutral bodies. In each case different results were obtained.

All the samples were completely soluble in amylic alcohol, ether, benzene, chloroform, carbon bisulphide, and aniline, but gave a more or less turbid solution

with olive-oil, in which, according to De Schulz, the pure oil is completely soluble. Turpentine should also dissolve the oil completely, but in none of the specimens examined by the author was there complete solution.

The results of other tests are given in the subjoined table, in which the names at the top of the columns are those of the firms which supplied the oil:

	Characteristics given by De Schulz.	Pelliot.	Poulenc.	Pharmacie Centrale.	P. Bounes.	Cabanis.
Density	0·9874 to 0 9904	1 at 20° C.	0·998 at 18·5° C.	1·031 at 14° C.	1·02 at 14° C.	0·998 at 25° C.
Viscosity (minutes)	?	105	60	270	360	32
Solubility in Alcohol 90 per cent.	Incomplete	Complete.	Complete	Turbid	Turbid	Turbid
Solubility in Acetic acid	Incomplete	,,	,,	Complete	Complete	Complete
Colour reaction of solution in ether (1 : 10) with copper acetate (1 : 1000)	Greenish	Nil	Nil	Nil	Red	Nil
Colour reaction of aqueous extract (1 : 10) with ferric chloride (1 : 1000)	Red	Vinous red	Onion-peel colour	Vinous red	Onion-peel colour	Onion-peel colour
Lime-water	Reddish-brown	Colour hardly perceptible	Nil	Yellow	Yellow	Onion-peel colour
Ammonia	Madder	Yellow	Madder	,,	,,	Yellow
Per cent. distilling below 250° C.	—	12	7	11	9	9
Between 250° and 275° C.	—	33	36	12	10	29
Between 275° and 300° C.	—	26	34	14	10	37
Above 300° C. and residue	—	30	27	65	72	28
		101	104	102	101	103

The fact that in every instance the total amount obtained on distillation was greater than the quantity taken is attributed to the rapid oxidation of the oil. The author considers that these results show that it is practically impossible to obtain a pure oil of cade, and that therefore that oil ought to be omitted from the Codex.

C. A. M.

ORGANIC ANALYSIS.

Detection of Formaldehyde. D. Vitali. (*Boll. Chim. Farm.*, 1898, xxxvii., 321; through *Chem. Zeit. Rep.*, 1898, 179.)—When an aqueous solution of formaldehyde is treated with a 4 per cent. solution of a salt of phenylhydrazine, a white precipitate is produced, and the mixture gradually turns yellow and then orange. The reaction is given instantly by 1 per cent. solutions; in 0·001 per cent. solutions it requires two or three hours to develop. The deposit is amorphous and dissolves in alcohol, crystallizing therefrom in rhombic tables. If the mixture of formaldehyde

and phenylhydrazine is allowed to evaporate spontaneously, a yellow residue is obtained, which finally becomes red; and on washing this with water, dissolving it in warm absolute alcohol, a yellow solution is produced which reduces gold salts, giving a green liquid that changes to red on addition of caustic soda. If the original mixture, immediately the precipitate falls, is treated with sodium nitroprusside and caustic soda, it yields a fine blue colour. Acetaldehyde does not give the reaction; and provided the latter is not present in too large proportions, it may be used for the recognition of formaldehyde therein. F. H. L.

Electrolytic Determination of Sugar. J. Formánek. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 320.)—This is substantially Allihn's method, but modified so as to render it easier of execution. The original process is followed exactly up to the point of the separation of the cuprous oxide. This is then filtered off through a good thick Swedish filter, which has been successively extracted by hydrochloric and hydrofluoric acids. The precipitate must be kept covered with liquid as completely as possible during the filtration and subsequent washing. It is washed with hot water and then dissolved in the smallest possible quantity of warm dilute nitric acid (specific gravity, 1·2), the acid solution and washings being collected in a weighed platinum basin. Ammonia is now cautiously added until a faint blue colour is produced, after which, for quantities of copper up to 0·5 gramme, 20 c.c. of ammonia of 0·96 specific gravity, and 20 c.c. of a 25 per cent. solution of ammonium nitrate, are added, and the solution diluted to about 150 c.c. For quantities of copper exceeding 0·5 gramme, 30 to 35 c.c. of ammonia must be used. On applying the current, the deposition of copper proceeds very rapidly, and is complete as soon as the last shade of blue disappears from the liquid. The basin is then washed out, at first without interrupting the current, and finally rinsed with distilled water and absolute alcohol. It is then dried for five minutes at 80° to 90° C., cooled and weighed. From the increase in weight, corresponding to the amount of copper, the sugar is found by reference to the tables.

The following results are given:

No.	Copper found.	Glucose found.	Glucose taken.	Difference.
1.	0·0948	0·0483	0·04865	− 0·00035
2.	0·0956	0·0487	0·04865	+ 0·00005
3.	0·0958	0·0488	0·04865	+ 0·00015
4.	0·1896	0·0971	0·0973	- 0·00020
5.	0·1901	0·09735	0·0973	+ 0·00005
6.	0·1906	0·0976	0·0973	+ 0·0003
7.	0·1896	0·0971	0·0973	- 0·0002
8.	0·1900	0·0973	0·0973	0
9.	0·1896	0·0971	0·0973	− 0·0002
10.	0·2790	0·1450	0·1459	− 0·0009
11.	0·2800	0·1455	0·1459	− 0·0004
12.	0·2795	0·1453	0·1459	− 0·0006

H. H. B. S.

Sugar Estimation according to Kjeldahl. Bruhns. (*Centralbl. Zuckerind.*, 1898, vi., 755; through *Chem. Zeit. Rep.*, 1898, 180.)—Kjeldahl's criticisms (ANALYST, xx., 227) on the processes for estimating sugar with alkaline copper solutions are no doubt well-founded when the conditions are such as those detailed in his experiments; but these conditions do not exist, or can easily be avoided, in practice. Access of oxygen to the surface of the liquid, even under the most unfavourable circumstances, does not appreciably affect the results of the analysis. F. H. L.

A Method for the Differentiation of Organic Matter in Water. A. G. Woodman. (*Journ. Amer. Chem. Soc.*, 1898, xx., 497-501.)—The author's objections to the Forchammer permanganate process and its modifications are: (1) That the results are comparative, and do not indicate the absolute amount of carbonaceous matter, and (2) that these comparative results are only of value when the organic matter in different samples is identical in composition.

Barnes (*Journ. Soc. Chem. Ind.*, 1896, 83) showed that organic matter underwent different degrees of oxidation with permanganate and chromic acid, and expressed the results in the form of a ratio between the amount of oxygen consumed in each case. For example, solutions of starch and of sugar are acted upon by chromic acid much more than by permanganate, thus giving a very low ratio. Gelatin and glycerin also give low ratios, whilst, on the other hand, infusions of peat and solutions of tannin give a high ratio. On these observations the author has based his method of determining the nature of the organic matter in water.

One hundred c.c., or more, of the water are mixed with 8 c.c. of dilute sulphuric acid (1 : 3), and about 10 c.c. of $\frac{N}{100}$ potassium permanganate (or more if the water was highly coloured) added from a burette. The liquid is heated to boiling, boiled for exactly five minutes, allowed to cool for one minute, 10 c.c. of $\frac{N}{100}$ oxalic acid added, and the excess of the latter titrated with the standard permanganate.

The solutions required for the chromic acid method are: (*a*) 6·2 grammes of potassium bichromate dissolved in water, and after the addition of 50 c.c. of concentrated sulphuric acid made up to a litre; (*b*) 18 grammes of crystallized ferrous sulphate dissolved in a mixture of 100 c.c. of sulphuric acid and 200 c.c. of water, and diluted to 500 c.c. This solution will not keep for more than two or three weeks.

Fifty c.c. of the water to be examined are mixed with 20 c.c. of sulphuric acid (specific gravity 1·84), and after the addition of exactly 10 c.c. of the chromic acid solution, heated for an hour on the boiling water-bath in a flask covered with a watch-glass. It is then allowed to cool for a few minutes, 10 c.c. of the ferrous sulphate solution added, and the whole poured into 500 c.c. of cold water and titrated with $\frac{N}{100}$ permanganate. A blank determination should always be made at the same time on 50 c.c. of water free from organic matter.

The results are expressed in the form of an "oxygen ratio" by dividing the number of c.c. of permanganate used in the first determination by the number required by an equal volume of the water in the chromic acid method. In general this ratio is in the form of a fraction less than unity.

In the investigation the author applied this process to the examination of natural waters which consumed a large amount of oxygen, but which were known to be free from sewage contamination, and also to filtered city sewage in various degrees of dilution. The results obtained with these "peaty" waters are given below, the colour being those of Leed's nesslerized ammonia scale.

	Colour.	Ratio.
Boston tap-water (July 24, 1897)	0·3	0·656
,, ,, (January 24, 1898) ...	0·7	0·646
,, ,, (March 11, 1898) ...	0·48	0·649
Colour standard (*a*)	5·00	0·833
,, ,, (*b*)	1·8	0·689
Reservoir Orange, Mass.	0·58	0·659
,, Athol ,, (full of algæ) ...	—	1·132
,, ,, ,, (filtered)	1·7	0·750
Infusion of dried leaves	about 10·0	0·656
Solution of humus in ammonia	—	0·692

Of these samples, the author remarks that the Boston tap-water is a typical brown surface water, and that the colour standards (*a*) and (*b*) were very dark-coloured swamp waters diluted.

The ratios obtained with sewage were about the same as those given by Barnes for nitrogenous substances:

	Ratio.
Sewage from Marlboro (filtered, old)	0·543
,, ,, Boston (decanted, fresh)	0·389
(*a*) Filtered sewage, Hereford Street, Boston	0·470
(*b*) Sewage (*a*) diluted with 5 vols. of distilled water ...	0·490
(*c*) ,, (*a*) ,, 10 ,, ,, ...	0·460
Well contaminated with sewage	0·449

From these results it is seen that peaty waters give a ratio above 0·600, whilst sewage and waters contaminated by sewage give a ratio below 0·600, which appears to be the dividing-line between the ratios of animal and vegetable origin. Moreover, the ratio is practically constant if the organic matter does not alter in character, however much the amount present may vary.

As a further test of the applicability of the process, two samples of water were prepared: (*a*) Containing considerable colouring matter of vegetable origin, but known to be free from sewage; (*b*) consisting of distilled water contaminated with sewage. The amount of oxygen consumed in the permanganate process by these samples was nearly identical ($a = 0{\cdot}2387$ and $b = 0{\cdot}2375$ parts per 100,000), but the ratios differed widely—$a = 0{\cdot}827$, and $b = 0{\cdot}372$.

The method was also tried on a well-water which appeared suspicious from the amount of oxygen consumed in the permanganate test. The ratio obtained was high —viz., 0·957—and from this the author concluded that infiltration of surface-water carrying vegetable substances, and not sewage, was the cause of the organic matter, a conclusion which was subsequently confirmed by an examination of the well.

C. A. M.

Detection of Cotton, Sesamé, and Arachis Oils in Olive-oil. M. Tortelli and R. Ruggeri. (*Chem. Zeit.*, 1898, xxii., 600.)—The authors find that by a still further modification of the process they have already described (ANALYST, xxiii., 179) for the detection of cotton-oil in olive-oil, they are able in one operation to discover the presence of sesamé and arachis, and even to determine the proportion of the latter. Twenty grammes of the sample are saponified with 50 c.c. of alcoholic potash (120 grammes in 1 litre of 90 per cent. spirit) on the water-bath; a few drops of phenolphthalein are added, and the liquid is neutralized with 10 per cent. acetic acid. Two hundred c.c. of a 10 per cent. solution of lead acetate and 100 c.c. of water are then heated to the boil in a wide-necked flask, the soap solution is run in gradually, and the whole is shaken for ten minutes in boiling water. When the lead soaps have all adhered to the walls of the flask, the clear liquor is poured off, the insoluble matter washed three times with 200 c.c. of water at 70° or 80°, cooled, dried with filter-paper, and extracted for twenty minutes with 220 c.c. of redistilled ether under a reflux condenser, with occasional agitation. The flask is next placed in running water for half an hour to allow the insoluble lead salts of the solid fatty acids to settle; and then the ethereal liquid, with as little of the precipitate as possible, is run through a filter into a separatory funnel, and the residue extracted as before with 100 c.c. of warm ether. The filtrate is decomposed with 150 c.c. of 20 per cent. hydrochloric acid, the aqueous portion drawn off, and another, or even a third, 100 c.c. of acid are added till the whole of the lead chloride is removed. The ether is washed twice with 150 c.c. of water, filtered, and distilled until 15 or 18 c.c. of liquid acids are obtained. Five or six c.c. of this residue are tested with silver nitrate for cotton-oil as previously described (*loc. cit.*), while the remainder is shaken with an equal volume of strong HCl and 2 drops of a solution of furfuraldehyde (1 gramme in 100 c.c. of 95 per cent. alcohol). In the presence of even 1 per cent. of sesamé-oil, the acid becomes red, the depth of colour being in proportion to the amount of the impurity. Under these conditions, both the Becchi test for the cotton-oil and the Baudoin test for the sesamé-oil are absolutely characteristic, since neither reaction is given by any other edible oil that may exist in the original specimen.

The rest of the insoluble lead soaps are then brought on to the filter, and the flask and precipitate washed with ether till all soluble matter is removed. The paper is pierced, its contents rinsed into a separatory funnel by means of ether, the liquid is made up to about 220 c.c., the fatty acids are liberated with 20 per cent. HCl as above, washed with water, filtered, and the solvent completely distilled off. One hundred c.c. of 90 per cent. alcohol and 1 drop of weak acid are added, the flask is closed with a cork bearing a thermometer, and the whole is shaken on the water-bath until the temperature reaches about 60° C. and a clear solution is produced. The flask is then placed on a sheet of white paper, and if the oil contains even less than 5 per cent. of arachis, as the liquid cools very fine glittering needles of lignoceric acid are deposited, which soon collect into clusters, together with a larger quantity of thin mother-of-pearl-like plates of arachidic acid. With the solitary exception of cotton-oil, when treated in this manner, other oils give no precipitate, at least during several hours' standing; and the deposit from cotton-oil cannot be

mistaken for that from arachis, as the former is amorphous and quite opaque. The temperature at which the crystals begin to appear depends on the proportion of arachis present, so that the thermometer affords a rough means of estimating the amount of impurity, as shown by the following table :

First crystals appear C°	35–38	31–33	28–30	25–26	22–24	20·5–21·5	18–20	16–17
